A problem which is being presented to the Engineering Profession for solution is the determination of the safe yield of "underground reservoirs", or the net annual supply which may be developed by pumping and Artesian flow without persistent lowering of the ground-water plane. The answer to this problem must soon be had throughout the Southwest, and particularly in Southern California, where the use of underground water has advanced most rapidly. The available surface supplies of the region are now used so extensively that future extension of irrigation must depend on the underground supply. Already, however, the growing popularity of ground-water supply for irrigation and the heavy drafts made possible by improved pumping machinery and cheap power are giving rise to conditions of dangerous overdraft on many of the so-called inexhaustible underground water supplies. Furthermore, in many of the sparsely settled valleys of the Southwest, where very limited ground-water supplies are available, preparations are being made to develop pumped water for irrigation far in excess of the safe yield. The writer has in mind such a valley, where, out of 90 000 acres of agricultural land, filed on in good faith under the provisions of the Desert Land and Homestead Acts, it can be said with reasonable certainty that not more than 2% can ever be put under cultivation. In addition to the use of underground water for irrigation, it is being developed extensively for municipal purposes. The City of Los Angeles derives its present supply entirely from an underground reservoir, the San Fernando Valley, and is preparing to develop a similar supply in Owens Valley to be held as a reserve in connection with the Los Angeles Aqueduct. A portion of the supply of both Oakland and San Francisco is developed from underground sources, and the possibility of increasing largely the ground-water supply derived from Livermore Valley for the latter city has been the subject of considerable debate among prominent members of the Society. The problem, therefore, is an important one, and on it depends, not only the safe investment of capital, but also the very life of large industries and communities.

The sources of underground water are so difficult of measurement and its movements are so hidden from view, that the solution of the problem, until very recently, has been merely a subject for speculation and theory. Within the past few years, however, the study of underground water supply has been given considerable attention by the

United States Geological Survey as well as by engineers who have had these problems to meet. Although the fact of the existence of these "underground reservoirs" has been established, their sources of supply and outlets recognized, and many data regarding well fluctuations have been accumulated, yet very little has been done toward developing methods of measuring the rate of recharge or studying the factors which limit the quantity of water which can be safely developed from underground reservoirs.

The writer has had opportunity to investigate a number of the important underground reservoirs of California, and in this paper he presents certain general principles which seem to him to be justified by the existing data. Although these principles may seem to be self-evident, yet the writer has no knowledge that they have ever been applied to the practical solution of the problem in hand. To show the possibilities of their application, therefore, he presents data and studies for an underground reservoir in Owens Valley, California, where it was desired to ascertain the quantity of ground-water that could be developed safely without overdraft. Much of this information has already appeared in print* in greater detail, but the writer believes that the subject is of sufficient importance, and the component studies are of wide enough technical interest to be presented to the members of the Society for discussion and expression of opinion.

General Principles.

The typical underground reservoir is, geologically, a structural basin filled with alluvial débris from the adjoining mountain ranges. These basins are the product of faulting accompanied by the uptilting of a crustal block from one side of the line of fracture. The formation is very common throughout the Southwest, reaching its most perfect development in the Great Basin region of Utah and Nevada, where the name "Basin-Range" has been applied to it. In California the basins are found in the valleys of the Coast Range and along the base of the Sierra Nevada, Sierra Madre, San Bernardino, and San Jacinto Ranges. The rock enclosing these basins is in most cases impervious to water and practically insoluble. Along the coast of California, shales and cemented gravels predominate, and are practically non-water-bearing in comparison with the porous gravels

* Water Supply Paper No. 294, U. S. Geological Survey, 1912.

filling the basins; and, in the interior of the State, the enclosing rock formation is largely granite. Most of the basins can be considered as closed except for a subterranean outlet usually known as the "Narrows". This occurs at the lowest point in the rock rim, where the gravels contract into a neck filling a narrow depression or canyon cut into the confining rock. The quantity of underground water escaping through such an outlet is usually very small, however, as has been shown by a number of well-known underflow observations. Hence, the underground reservoirs can generally be considered as closed rock basins, the effective storage capacity of which is the void spaces between the particles of sand and gravel with which they are filled.

The usual sources of supply for underground reservoirs are percolation from flowing surface streams, from precipitation, or, where the supply is not ground-water derived from the basin, from irrigation on the surface of the porous gravels. The water thus absorbed sinks downward to the general ground-water plane and then moves laterally toward the region of lowest depression. This region, in contrast to the surrounding dry soil or desert, is usually characterized by springy, swampy conditions, and is commonly known in Southern California as a cienaga. The natural outlets for underground water are by springs or seepages discharging into the surface channels which drain the cienaga, by evaporation from damp soils and vegetation within the cienaga, and, to a limited extent, by underflow from the basin. The surface streams formed by the oozing out of underground water join to form a larger stream, which in all respects corresponds to the outlet of a lake or reservoir, and, passing from the basin, pursues its course just as any other surface stream. Its flow is characterized by permanence and regularity, except as it is augmented by surplus flood water which, during a limited period following winter storms, passes from the basin without being absorbed by the gravels.

The general principles of inflow into and outflow from an underground reservoir of the type described correspond with those of surface reservoirs. The difference lies in the relative speeds with which the general water surface assumes a horizontal position following increase or decrease of volume stored. In the case of a surface reservoir or lake, the effect of inflow or outflow is an immediate complete readjustment of surface level. The frictional resistance offered by the

particles filling an underground reservoir is so great, however, that the movement of water from an area of high level is very slow, varying from a few hundred feet to a few feet per day, depending on local conditions. As a result, the water surface in an underground reservoir is never horizontal, being steepest near the mouths of the mountain canyons, the run-off from which is the most important source of supply; it is most nearly horizontal at the region of outlet; and varies in slope and elevation from time to time, depending on the rate of recharge.

The average rates of inflow and outflow of an underground reservoir must be equal, otherwise there would be persistent rise or fall of ground-water levels until such a balance is reached. There are, therefore, two possible methods of measuring the rate of recharge, either by determining the total percolation from various sources into the porous material of the basin, or by determining the ground-water losses. The first method is to be preferred where the source of percolation is almost entirely stream flow from which channel losses can be accurately measured; or where the precipitation is large, well distributed through the year, and forms the principal source of supply. The first of these conditions could occur only in an arid region, and the second is typical of humid regions.

The method by determination of ground-water losses is one peculiarly adapted to arid or semi-arid conditions with high evaporation rate, such as exist throughout the Southwest. It has been the writer's observation in this region that soil evaporation and transpiration constitute from 50 to 100% of the ground-water losses from underground reservoirs, the average exceeding 75 per cent. Other losses are largely the flow from springs and seepages, which can be measured with precision. Rates of soil evaporation and transpiration from grasses do not present insurmountable difficulties of measurement under arid conditions. In fact, it has been the writer's experience that satisfactory results with specially designed equipment could be obtained from observations extending over 2 years, although a period of 3 years is preferable. Furthermore, the area from which evaporation occurs and the depth to ground-water at various points within it are not subject to wide fluctuations, and are easily measured. The determination of the rate of recharge of underground reservoirs of the basin type, therefore, is a problem of soil evaporation, transpiration, and stream

flow, all of which processes, with the exception of transpiration from trees, are now capable of measurement with relative accuracy at reasonable cost.

The general method pursued in the Owens Valley studies was to ascertain, by extended field measurements of soil evaporation, transpiration, and spring discharge, the average rate of outflow from the basin. All available evidence seemed to indicate that the basin was closed, so that the rate of outflow equalled the rate of inflow or recharge. As a check, therefore, the rate of inflow into this basin from precipitation, stream flow, and irrigation was also determined. The data are presented under the following headings: Physical Features, Precipitation, Stream Flow, Evaporation and Transpiration, Groundwater, and Rate of Recharge by Percolation.

Physical Features.

General.—The Owens Valley lies in east-central California, along the western border of the Great Basin, and at the base of the steep slope of the Sierra Nevada Mountains, as shown by Fig. 1. Including a northern extension, known as Long Valley, its length is 120 miles, and its width, from crest to crest of confining mountain ranges, varies from 15 to 40 miles. The total area of the valley and its tributary mountain drainage is about 3 300 sq. miles, of which 1 200 sq. miles are desert mountains from which the run-off is negligible, 536 sq. miles comprise the Sierra Nevada slope, which yields a large run-off, and 1 580 sq. miles are the transition slope and valley floor, from which very slight surface run-off occurs. The elevation of the valley floor varies from 8 000 to 3 570 ft. above sea level, the latter being at Owens Lake, the lowest depression of the valley. The average elevation of the crest of the Sierra Nevada is 12 500 ft., with many peaks exceeding this elevation by more than 1 500 ft. The White and Inyo Mountains, a desert range bordering the valley on the east, have an average elevation of 10 000 ft., with peaks reaching 13 000 ft.

The valley is a deep structural trough filled with porous alluvial material derived principally from the Sierra Nevada, and inclosed by impervious rock formations. The steep east face of the Sierra Nevada is the result of faulting accompanied by elevation and westward tilting of a great crusted block. The drainage system of the valley consists of a trunk stream, Owens River, fed by approximately

forty tributaries entering at fairly regular intervals from the west. The river terminates in Owens Lake, an alkaline body of water without outlet which disposes of all surplus surface water from the valley by evaporation. Irrigation is necessary for the production of crops, and water is diverted in canal systems from Owens River and tributary streams.

Independence Basin.—The portion of Owens Valley which is the subject of this study will be spoken of as the Independence Basin (Plate II). It lies in the south-central part of the valley, embracing with its tributary drainage area the region between the Sierra Nevada crest and Owens River, lying between Poverty Hills on the north and Alabama Hills on the south. These latter are secondary ranges extending into the valley from the Sierra Nevada and isolating a portion of the valley fill about 25 miles long and from 6 to 8 miles wide.

For the purpose of this study, the surface of the region has been classified as high mountain drainage, intermediate mountain slopes, outwash slope, and valley floor. (Table 1 and Plate II.)

TABLE 1.—SUBDIVISIONS OF INDEPENDENCE REGION.

Subdivision.	Area.		Boundary.		Slope.	Vegetation.	Character of surface.
	Square miles.	Percentage of total.	Upper.	Lower.			
High mountain drainage.	96.0	27	Sierra crest.	Mouth of canyon.	Precipitous to gentle.	Isolated forest trees.	Bare granite and fragmental rock accumulations.
Intermediate mountain slope.	29.4	8	Canyon drainage.	6 500-ft. contour.	2000 to 3000 ft. to the mile.	Desert bushes and nut pine.	Fragmental and finely disintegrated rock accumulations.
Outwash slope.	165.3	46	6 500-ft. contour.	Grass land.	300 to 600 ft. to the mile.	Desert bushes.	Boulders, sand and gravel.

	357.1	100					

The high mountain drainage embraces the eastern slope of the Sierra Nevada and consists of a series of seventeen small canyons which are the drainage basins of streams tributary to Owens River (Table 2). These canyons are all narrow at the mouth (the 6 500-ft. level) and broaden out more or less toward the summit, presenting a roughly triangular shape. They are separated by high knife-edge ridges, which terminate in triangular slopes facing the valley. They have been cut by water erosion and sculptured by active glaciation above the 7 500-ft. level, their upper portions being well-developed glacial cirques. In many places below the cirques are series of benches occupied by glacial lakes or meadows. Most of the cirque floors are buried beneath morainal accumulations; some of the polished canyon bottoms between the 11 500 and 8 000-ft. levels are swept clean of débris, and others are completely buried by morainal material. Terminal and lateral moraines of considerable size occupy the canyon floors between the 8 000 and 7 000-ft. levels.

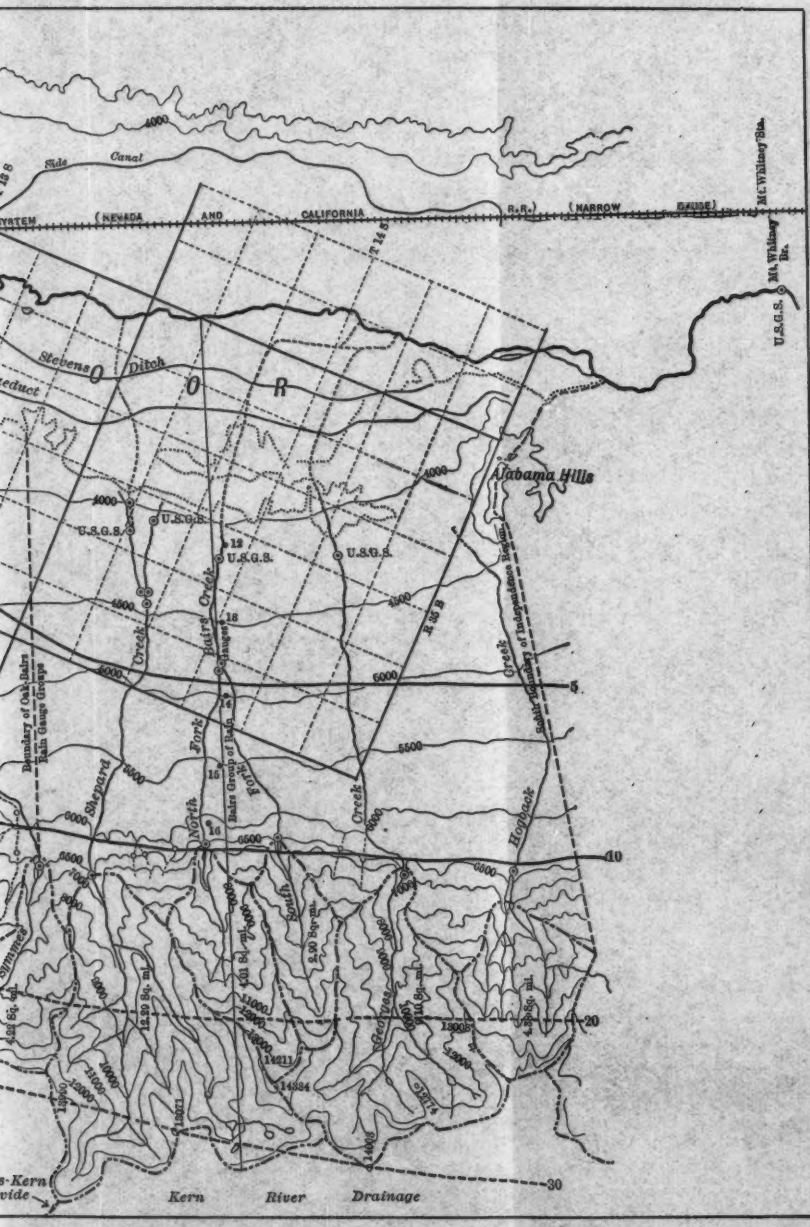
PAPERS, AM. SOC. C. E.
APRIL, 1914.
LEE ON
YIELD OF UNDERGROUND RESERVOIRS.



The intermediate mountain slopes (Fig. 2) are the triangular areas terminating the ridges between the canyons, and probably represent the original face of the range before it had been actively eroded (Table 3). Their lower boundary has been arbitrarily placed at the 6 500-ft. contour, and their apexes reach a maximum elevation of about 12 000 ft. They have a steep uniform slope of from 2 000 to 3 000 ft. to the mile, and in general are covered with a mantle of disintegrated rock and slide material which merges into the valley fill.

TABLE 3.—INTERMEDIATE MOUNTAIN SLOPES OF INDEPENDENCE REGION.

	29.45	.....	.....	.....	.....	

The outwash slope (Fig. 2) is the desert portion of the surface of the valley fill, extending from the 6 500-ft. contour at the base of the Sierra Nevada to the upper edge of grass and irrigated land in the valley (3 900 to 4 000 ft.). Its surface is composed of loose boulders, gravel, and sand, deposited during past ages by torrential streams coming from the mountains. This deposit is of

unknown depth, and lies on a buried ancient rocky surface, the higher hills of which appear above the present surface as buttes or knolls. The channels of streams draining the mountain canyons cross this slope in trenches, which, near the mountains, are from 25 to 50 ft. deep.

The valley floor embraces the area between the outwash slope and Owens River, and its surface may be classified as irrigated land, grass or meadow land, alkali land, and desert. The upper edge has a maximum slope of about 120 ft. to the mile, but within a short distance it merges into the practically level valley. The surface is soil to a depth of from 1 to 3 ft., except on the desert land, where it is fine sand. Most of the irrigated land is along the upper margin of the valley floor adjoining the creek channels. The grass or meadow lands lie between and to the east of the ranches, and extend well out into the level valley. The growth is most luxuriant in the spring zone, which is about ¼ mile wide and is at the upper edge of the valley floor. Here are numerous small flowing springs, with temperature of about 62°, which start the meadow grass early in the season and keep it green until late in the autumn. Farther out in the valley, the salt grass makes a green carpet from May until late July. In the salt-grass land there is always a deposit of alkali about the plant roots, and the soil surface is crusted. The spring zone, however, is free from alkali. The worst alkali land is practically bare of vegetation and is thickly crusted with white salts. It lies in the more level areas in the center of the valley.

The desert area to the east of Owens River yields no appreciable run-off, and, owing to its light precipitation, it makes no contribution to the ground-water.

The alluvial material which forms the valley fill varies in size from large boulders to fine clay, and, in arrangement, from a thorough mixture of all sizes to layers of well-assorted gravel, sand, and clay. The transporting medium was water, both mountain streams and Owens River taking part in the work. Some of the material was deposited in the beds and on the sides of shifting stream channels, and much of the finer sand and clay was deposited from the quiet waters of a large lake which occupied the lower portion of the valley. The structure of the valley fill, therefore, is complex, and the character of the alluvial material underlying a given locality is difficult to determine without actual examination from borings.

FIG. 3.—EVAPORATION FAN IN OWENS RIVER.

FIG. 4.—EVAPORATION FAN IN SOIL.

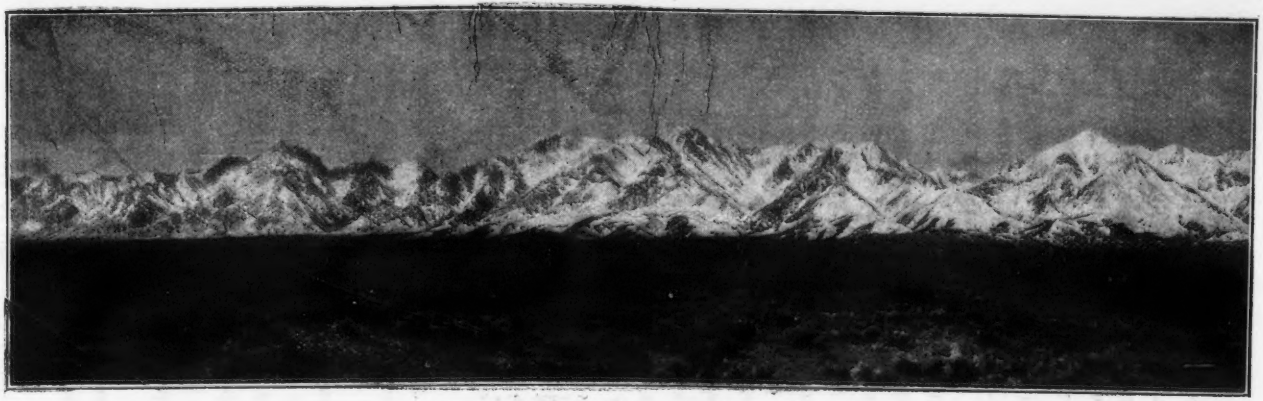

FIG. 2.—EASTERN SLOPE, SIERRA NEVADA.

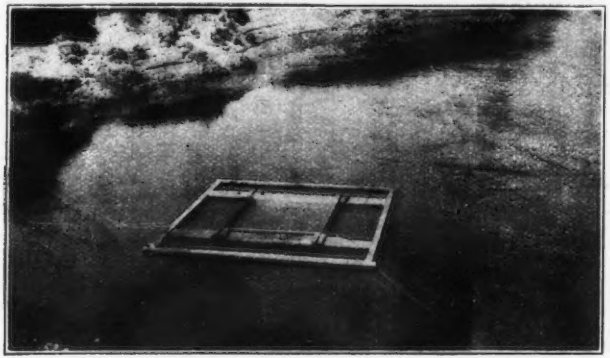

FIG. 3.—EVAPORATION PAN IN OWENS RIVER.

FIG. 4.—EVAPORATION PAN IN SOIL.

A number of borings, ranging in depth from 250 to 500 ft., have been made in the basin by the City of Los Angeles, in connection with the development of the aqueduct supply. In general, the materials encountered were clay, sand, and coarse gravel in layers varying in thickness from a few inches to 150 ft. Coarse material in thin layers interbedded with clay predominates along the upper edge of the valley floor in the spring belt. All wells in this belt yield Artesian flows of from 1 to 2 sec-ft. The material is progressively finer and occurs in thicker strata east of this belt, toward the center of the valley, and the Artesian flows decrease in volume. Near Owens River, fine sand and clay in alternate layers is the only material encountered above the 300-ft. depth.

The streams from the Sierra Nevada were by far the most active in the work of building up the valley fill. Their loads were acquired in the mountain canyons and carried out into the valley, where they were dropped in order of size as the velocity of flow decreased. The old lake level stood at an elevation of about 3 790 ft. for a long period, as shown by beach lines on the east slope of the Alabama Hills. The present 3 790-ft. contour lies near the spring and Artesian belt. The finer materials between the spring belt and Owens River are evidently lake deposits. The ancient lake was contemporaneous with other geologic lakes of the Great Basin, such as Lakes Bonneville and Lahontan. The geologic history of these lakes shows many wide fluctuations of water level, covering long periods of time. The interbedding of fine and coarse material encountered in the spring belt is evidently the result of such fluctuation, as the sudden checking of the velocity of a stream on entering a body of still water results in the immediate deposition of coarse material. The Artesian and spring conditions, therefore, result from hydrostatic pressure on the water entrapped in these wedges of coarse material.

Two cross-sections of the valley, showing the probable geologic structure, were constructed along the Thibaut and Independence Sections (Fig. 5). The topography for these sections was obtained from the U. S. Geological Survey's map of the Mount Whitney quadrangle, and the character of the surface material was determined by field inspection. The exposed slopes of bed-rock on each side of the valley were joined beneath the valley floor, and the arrangement of the material filling the basin thus formed was represented according to

the best available knowledge, the strata of fine material being indicated by solid black. On the diagram, the greatest depth of alluvial filling measures 2 500 ft. in the Independence Section, and 1 800 ft. in the Thibaut Section. Two of the aqueduct wells near the Independence Section reached depths of 500 ft. in alluvial material, and a well drilled by the Southern Pacific Company, opposite the Alabama Hills at Lone Pine Station has reached a depth of 832 ft., entirely in fine sand. There is no reason to suppose that the gravel filling near Independence is less than 2 000 ft. in depth.

The volume of void space, or porosity, of a body of alluvial material of this type is variously estimated by different authorities at from 20 to 35% of the total. Samples of the mixed gravel, sand, and silt of the outwash slopes west of Independence were removed to a depth of 4 ft., without disturbing the natural arrangement of the particles, and weighed dry and after saturation. The results of these tests indicate a porosity of 28% for these samples. The presence of very coarse gravel and boulders in this material would reduce the porosity, and, for the valley fill as a whole, 25% is probably more nearly correct.

Precipitation.

The plan followed in the study of precipitation was to gather and assemble data from which to prepare isohyets for the basin. These appear on Plate II, and are based on the available precipitation data and an intimate knowledge of the local topography and vegetation.

Observations of precipitation were made in the Independence Basin as early as 1865, under the direction of United States Army officers stationed at Fort Independence. The record extends unbroken from September, 1866, to August, 1877, and was obtained under conditions sufficiently similar to permit of combining it with the more recent Weather Bureau record at Independence. The latter covers the periods from September, 1892, to August, 1895, and from September, 1898, to August, 1910, so that there are 26 seasons for which precipitation records are available at Independence. To supplement this record, twenty standard Weather Bureau rain gauges were established, and observations were made during the seasons 1908-09 and 1909-10 (Plate II). These gauges were distributed systematically over the valley floor and outwash slopes, and could all be reached during one day by three mounted observers stationed at points

in the valley where shelter was available. Four records were also available in Owens Valley, outside of the Independence Basin, at Bishop, Lone Pine, Laws, and Keeler. The Bishop and Lone Pine records are kept by co-operative Weather Bureau observers, and cover 15 and 5 years, respectively. The Laws and Keeler records are kept by railroad agents, and are for 13 and 24 years.

The distribution of total precipitation, with respect to geographic location, in the Independence Basin and adjoining areas depends to a great extent on topographic features, notably mountain ranges and valleys, although a consistent variation is also evident with changes in latitude. The controlling topographic feature is the Sierra Nevada, which has a general northwest and southeast trend.

This relation of precipitation and topography is well shown by studying observations made along cross-sections of the Sierra Nevada laid out at right angles to the trend of the range. Two such sections are indicated on Fig. 1 as the Central Pacific and Mokelumne Sections. The relations of mean annual precipitation, altitude, topographic position, and profiles of ground surface are presented graphically for the two sections in Diagrams 1 to 6 of Plate III. The marked similarity in the curves for the two sections indicates that the quantity of precipitation at points in a transverse section of the range conforms to some general law. Elevation, obviously, is not the controlling factor, for above the 5 000-ft. level the precipitation decreases with increase in altitude. The slope of the ground surface appears to be the most important element involved, as is seen from Diagrams 2, 3, 5, and 6 of Plate III. The phenomenon results from the condensation of aqueous vapor due to adiabatic cooling of masses of moist air driven up the slope of a mountain range by the prevailing winds. The region of maximum precipitation is at the lower cloud limit on the windward slope of the range, and above this the latent heat liberated by condensation raises the temperature above the dew point, resulting in decreased precipitation. After crossing the summit of a high range, the descending mass of air contracts in volume, thereby raising the temperature rapidly above the dew point and resulting in marked decrease of precipitation.

The increase of precipitation with elevation was first observed by Mr. S. A. Hill.* in studying rainfall in the northwest Himalayas of

India, and he developed for that region the empirical formula, $R = 1 + 1.92h - 0.40h^2 + 0.02h^3$, in which R represents the quantity of rain and h the relative height, in units of 1 000 ft., above an assumed plane which is itself 1 000 ft. above sea level. This equation, when platted, gives a curve very similar to that shown in Diagrams 1 and 4 of Plate III, the plane of maximum rainfall being 4 160 ft. above sea level. The equation does not apply to conditions on the leeward slope of a range, however, to judge by the discontinuity at the crest line shown on the Sierra Nevada curves. The straight-line relation between precipitation and elevation, which is often assumed in engineering computations, thus appears to have a very limited use, and to be at best a rough approximation.

The Los Angeles Aqueduct precipitation stations in Owens Valley lie in three groups, indicated on Fig. 1 and Plate II, as the Taboose, Oak, and Bairs Sections. The 2-year records for these stations were reduced to averages by comparison with the 26-year record at Independence. The platted curves for these sections (Plate III) are all similar in shape, and agree with the desert slope portion of the Central Pacific and Mokelumne curves. The highest point on each of the Owens Valley curves was obtained from the measured run-off of the canyons crossed by the section and a run-off factor chosen after careful study of precipitation and run-off data for Kings River, which drains the slope of the Sierra Nevada to the west. The precipitation at the mouth of the canyons was known from the rain gauge observations, and the average precipitation over each canyon from the run-off. Most of these canyon drainage areas are isosceles triangles in plan, the base being along the crest of the mountains. Also, judging by the Central Pacific and Mokelumne Sections, the precipitation increases uniformly from the base of the mountains on the desert side to the summit. Hence, the precipitation at the center of area of each drainage basin is equal to the average precipitation over the whole area, and the precipitation at the summit is obtainable by a simple proportion.

Preliminary to the establishment of isohyets or lines of equal annual precipitation for the Independence Basin, a broad study of precipitation was made for the whole Sierra Nevada range from Lake Tahoe to the Mojave Desert (Fig. 1). This was based on the California Water and Forest Association rainfall map of the State, pre-

pared in 1900, as revised between American and Kings Rivers by Edwin Duryea, Jr., M. Am. Soc. C. E., in 1908. With all available rainfall data to date, including the Los Angeles Aqueduct and several private records, the writer has made further revisions over the Southern Sierra and Owens Valley. The Water and Forest Association isohyets, as amended by Mr. Duryea, appear on Fig. 1 as solid lines, and revisions proposed by the writer are represented by dotted lines. Isohyets are shown with greater detail for the Independence Basin on Plate II.

Stream Flow.

Stream flow data essential to the determination of inflow and outflow for an underground reservoir, are the run-off from precipitation, the seepage from or into stream channels, and the flow of springs. Precipitation which finds its way into surface streams without absorption may, along some portion of the channel, percolate into porous gravels and join the subterranean supply. On the other hand, water may escape from the underground reservoir by seepage into stream channels where the general water plane is at a higher elevation than mean water level in the stream. Escape may also occur from springs.

The problem in the Independence Basin was, first, to classify the surface as to run-off characteristics and determine the run-off from each subdivision; second, to ascertain seepage losses from the seventeen tributary mountain streams between the canyon mouths and the valley floor; third, to determine the flow of springs which represent water escaping from the basin; and fourth, to ascertain whether Owens River made or lost water in passing through the basin.

Run-off.—It was early observed that the run-off characteristics of the four areas into which the region was classified for study (Table 1) were similar.

The clay soils of the valley floor occasionally yield a small run-off during and following winter precipitations of 1 in. or more in 24 hours, or warm rain falling on old snow. This water gathers and passes off into Owens River within a few hours by way of four waste channels. A study of the available data shows that the average total run-off from precipitation on the valley floor is about 2 sec-ft. of continuous flow.

The outwash slopes yield no appreciable surface run-off, on account of the porous gravel formation and the great depth to ground-

water. This fact has been established by repeated observations during and after rainstorms and thaws, and is confirmed by the noticeable absence of recent drainage channels or washes, except those of streams which derive their water from high mountain drainage areas.

The intermediate mountain slopes yield a small run-off during May and June, when the temperature at that level is sufficient to melt the accumulated winter snow, but the small streams do not advance far over the outwash slopes before they are entirely absorbed. If the precipitation of the preceding winter is below normal, the snow melts before the hot weather comes, and is absorbed at once. Springs are common along the lower borders of these slopes, the source being the melted snow absorbed by the porous material above and brought to the surface where it comes into contact with impervious formations. In only a few places does such water find its way into living streams.

The high mountain drainage areas have an abundant run-off, and perennial streams flow from all but one of them. The source of this water is precipitation, in the form of snow and rain, which falls within the drainage areas, and to a small extent snow dust carried over the summits by the prevailing west and northwest winds of winter and spring. For all practical purposes, the average discharge at the mouth of the canyon represents the average precipitation within the drainage area minus losses by evaporation from exposed snow surfaces. The underflow from these areas is negligible.

Stream discharge from the canyons is at a minimum from September to April. The flow during these months is remarkably uniform, and is entirely uninfluenced by the current storms, though from 70 to 80% of the annual precipitation occurs between November 1st and March 31st. The low-water flow is derived from springs and from the slow melting of the snow layer exposed to the earth's latent heat. Streams are usually frozen over by November, and as late as April they flow nearly to the mouths of the canyons in tunnels under the snow. Between April 1st and 20th air temperatures increase sufficiently to melt the snow at the lower elevations, and the streams begin to rise. There is an increase in air temperatures and stream flow from this date until the maximum flood crest is reached, some time between June 15th and July 15th, depending on the quantity of snow to be melted. Stream flow then decreases until some time in September,

after which low water prevails. About 70% of the annual run-off of the streams occurs during May, June, July, and August.

Percolation from Stream Channels.—The United States Geological Survey gauging stations on streams draining the high mountain areas are at the lower edges of the outwash slopes, just above the division boxes which apportion the water for use on the ranches of the valley floor. After leaving its canyon each stream traverses several miles of channel before reaching the gauging station, and preliminary observations in June, 1908, showed that considerable water (in some streams 50%) disappeared between the two points. It was necessary, therefore, either to establish regular gauging stations at the canyon mouths and depend on records for short periods, or to devise some means of computing the run-off from the high mountain areas from the existing Government records, which extended over 6 years. The latter method was chosen, and the results have proved very satisfactory.

The loss from these stream channels occurs as percolation into the porous alluvial material, direct evaporation from water surface, and transpiration from vegetation growing along the stream borders. Evaporation and transpiration losses were too small to be detected in current-meter work. As the expense of installing and maintaining weirs was prohibitive, the problem resolved itself into a study of percolation from stream channels.

There are three factors to be considered in a study of the subject: the rate of percolation, the area through which percolation occurs (the wetted perimeter), and the period of time during which a given unit of water is exposed (velocity of flow). The rate of percolation depends on (1) the character of the channel lining and the medium surrounding the channel, as regards size of pores and porosity; (2) the pressure gradient, depending on the difference in level of the surface of the water in the channel and the ground-water surface; and (3) the temperature of the water.

The effect of an increase in the wetted perimeter, other conditions being the same, is obviously to increase the percolation, but such change is accompanied by a proportionally larger increase in the velocity of flow, which reduces the time of exposure of a given volume of water. The net result, considering the total flow, is, therefore, a proportionally smaller percolation, although this effect may be counter-

acted to a certain extent by the scouring of a non-porous channel lining due to the increased carrying power of the stream. The whole matter is affected by so many indeterminate conditions that a general mathematical analysis is impossible, but, with these ideas in view, a study was made of each channel within the ordinary range of temperature and discharge.

The field work consisted of making comparative current-meter measurements at upper and lower stations on each creek, giving proper allowance of time for the passage of water between the two points. The measurements were made at intervals of from 6 weeks to 2 months, and extended over the period from June 15th, 1908, to September 15th, 1909, including the high-water periods of wet and dry seasons. Gauging sections were prepared at the mouth of the canyon on each creek. Estimates of the time required for the passage of water between stations were based on actual trial with aniline dye. Very little fluctuation in discharge was observed in any of the creeks between 8 A. M. and 5 P. M., even in the high-water period.

The temperature of the water as it issues from the canyons varies from 35° to 42° Fahr., in winter, and from 48° to 53° Fahr., in summer. In winter the temperature does not increase much as the water travels toward the valley. After leaving the protecting cover of the snow in the canyons during December and January the water actually becomes colder, ice prevailing for several weeks. In summer there is an average increase of 10° between the stations at the mouth of the canyon and in the valley.

Several methods were attempted for generalizing the results, but the most satisfactory was a graphical one, in which losses were platted as abscissas and stream discharges as ordinates with rectangular coordinates (Plate IV).

It was found that for each channel a straight line expressed the relation of these two quantities from April to October, inclusive. During the remaining 5 months, the relation is not clear, but the total loss is then so small that it can be obtained by inspection without affecting the accuracy of the computed discharge at the mouth of the canyon. Total losses are platted on the basis of discharge, both at lower and upper stations, so that, in correcting the Government records to obtain the true yield from high mountain drainage areas, the quantity desired can be obtained at once by entering on the X-axis

the discharge at the lower or Government station. It is also possible at the same time to read the loss, in second-feet to the mile, from the straight line below the X-axis.

The diagrams on Plate IV were prepared for the purpose of computing (1) seepage losses above the U. S. Geological Survey gauging stations, and (2) the actual yield of high mountain drainage areas. In obtaining the field data, discharge measurements were made with small Price current meters during the period, June to August, 1909, inclusive, covering a season of small run-off and one of large run-off. The accuracy is up to the standard for a stream of this type. Measurements of medium and high stages were difficult, on account of the rough sections and very high velocities. The upper gauging station is at the mouth of the canyon, or below impervious dikes forcing seepage water to the surface. The average elevation is 6 000 ft. The lower station is that used by the U. S. Geological Survey (unless otherwise noted), which is above the diversion and has an average elevation of 4 100 ft. Below the latter there is ½ mile or more of channel suffering a large seepage loss which is not included. The length of the channel was obtained by scaling from the Mt. Whitney Quadrangle, and, for Taboose, Red Mountain, and Tinemaha Creeks, from a triangulation survey. Elevations were obtained in a similar manner. In using the diagrams, the straight-line relation applies from April to October, inclusive, during which time temperature and discharge vary similarly. The dotted portions are not supported by field data, and are to be used with judgment. From November to March, inclusive, temperature is the only effective variable, and arbitrary values for loss have been selected. Line "A" expresses the relation of total loss to discharge at the U. S. Geological Survey Station; Line "B" expresses the same relation at the mouth of the canyon; and Line "C" expresses the loss per mile to discharge at the mouth of the canyon. The diagrams are arranged so that all the four values involved may be obtained by entering any one of them.

There are some interesting conclusions to be drawn from these diagrams. In general, the quantity of water percolating from the channels studied varies with the time of year and with different channel conditions. Variation with the time of year is due to the combined effects of temperature, area of wetted perimeter, and velocity of flow. These work more or less in harmony during April to October, inclusive.

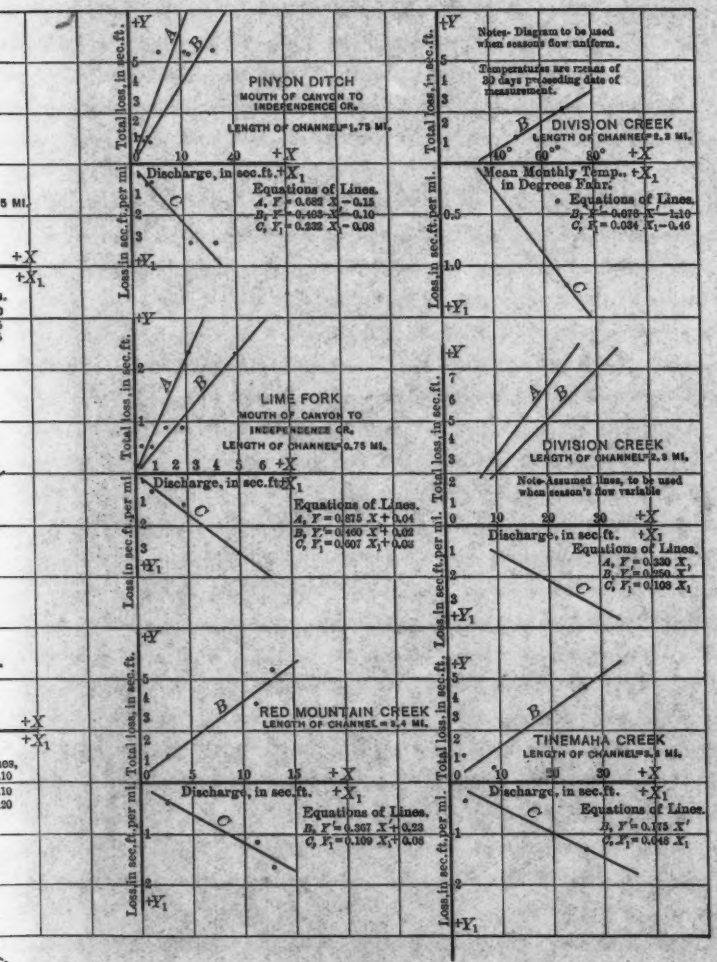
N THE VICINITY OF INDEPENDENCE



UNIV. OF MICH.

and produce the straight-line relation of total loss and discharge. From November to March, inclusive, canyon discharges remain practically constant, showing that variations are largely controlled by temperature. Discharges are then so small, however, that errors of measurement are appreciable, and losses by evaporation have greater weight, so that the true relation of loss and temperature does not appear. A possible relation between total loss and temperature is suggested by the results on Division Creek, where the discharge at the mouth of the canyon was practically uniform during the period of study. Using as ordinates the mean air temperature at Independence for the 30 days preceding each date of measurement, we obtain a straight line which crosses the X-axis at about 35 degrees. A line supported by additional data might cross nearer 32°, the temperature at which percolation becomes physically impossible.

The character of the surrounding medium was the only channel condition which noticeably affected percolation. The loss from a channel crossing fissured lava, even where the lava was covered by a thin sheet of alluvium, was 30% greater than that in coarse alluvium. The streams studied do not overflow their channels, so that the effect of varying channel slopes and wetted perimeter could not be studied.

The run-off from each mountain canyon was computed from U. S. Geological Survey monthly mean discharge records, by use of the diagrams. The results are summarized in Tables 4 and 5. The missing seasons were estimated from the unbroken records of neighboring streams after a detailed study of yield per square mile and annual departure from normal for each stream. The long-term mean discharge was obtained by comparison with the Kings River record, which covered 21 years. This stream was chosen because its drainage area adjoined most of the Owens Valley streams and because conditions affecting run-off were more nearly similar than on any other stream. The results indicate that the total annual mountain run-off during the period of record was 153 annual sec-ft. and the normal 130 annual sec-ft. This total does not include Red Mountain and Tinemaha Creeks, which pass out of the basin after crossing a portion of the outwash slope. The normal run-off per square mile for streams north of the Kings-Kern divide with 60% or more of area above 10 000 ft., is 1.75 sec-ft., and, for streams similarly situated, with less than 60% above 10 000 ft., 1.18. For streams south of the Kings-Kern divide,

the normal run-off is 1.36 and 0.86 sec-ft., respectively. It is also of interest to note that only 65% of this run-off reaches the Government gauging stations.

Springs.—The occurrence of springs in the basin is due to the reappearance of water which originally fell within its boundaries as precipitation and was absorbed. There are, in general, three types of springs which give rise to surface streams: those which derive their supply from precipitation on the intermediate mountain slopes, and appear at the base of these slopes; those which derive their supply from precipitation and stream percolation, and appear along the upper edge of the grass land; those which derive their supply from precipitation on lava flows, and appear at the lower borders of the flows.

The springs of the first type are not deep seated; they represent the drainage from the superficial deposits lying on the triangular mountain slopes between canyons. The temperature of their water is about 47° or 48° Fahr., and the flow in many of them increases in early summer and decreases during late summer and autumn. The water from most of these springs sinks into the porous gravels of the outwash slope, and joins the main body of ground-water in the basins.

The line of springs along the upper edge of the grass land represents the intersection of the natural surface of the ground and the surface of the ground-water. The water has penetrated rather deeply into the gravel fill, and issues with a temperature of about 62° Fahr., which is 5° higher than the mean annual temperature at Independence and 1° lower than that of water flowing from Artesian wells in the same location. The flow of these springs is variable, being least in late summer and greatest in early spring, with regular fluctuation between these dates, evidently depending on ground-water stages within the grass area. Only during the winter months is the discharge sufficient to be the source of surface streams which flow any considerable distance, and even then there are only a few of such streams which reach Owens River. Most of the yield of these springs is lost by evaporation and transpiration. The winter discharge of individual springs varies from 0.5 sec-ft. down to a quantity which is only enough to fill small pools of standing water, from which the evaporation equals the yield. The total winter discharge from all these springs is about 4 sec-ft.

The springs issuing from the lava formations are unique in having uniform discharges throughout the year and a temperature of 57° Fahr. The water is probably derived from precipitation on the lava surface, absorbed by the porous rock, and, by reason of the peculiar formation, gathered and delivered at the lower margin of the flow. The largest of these is Blackrock Springs (Plate II), 9 miles north of Independence. It has a discharge of 23 sec-ft., which flows out across the valley floor in two sloughs, each emptying into a series of shallow lakes. From November to March, inclusive, an average flow of about 7 sec-ft. reaches Owens River, but during the remainder of the year all the water is lost by seepage, evaporation, and transpiration. Hines Spring is 3 miles north of this spring, and has a continuous yield of about 4 sec-ft. Approximately, 1 sec-ft. finds its way into Owens River during the winter, but is lost during the remainder of the year. Campbell Spring is east of Owens River, 1 mile north of Aberdeen. It has a yield of about 0.5 sec-ft., and discharges directly into the river. Upper and Lower Seeley Springs are just above and just below Charlies Butte, and discharge directly into Owens River. The upper spring has a flow of 9.5 sec-ft., which is included in measurements of Owens River at the Butte. The lower one has a flow of 1.5 sec-ft.

Owens River.—Owens River flows lengthwise of the Independence Basin for 29 miles, although the actual length of its channel is possibly 20% greater, owing to its sinuosity. It is the drainage outlet for the waste surface water of the region, including the run-off from the valley floor, the yield of springs, and a small portion of the run-off from high mountain drainage areas. In order to account for all escaping surface waters, and determine the condition of the river channel with regard to seepage, observations of river discharge were made daily near the north and south boundaries of the region, and measurements of discharge into and diversion from the river channel were made between these two points. Complete data are available for 1909 and 1910. Analysis of these data shows that seepage losses occur during high-water, and seepage gains during low-water stages. The net result is a loss between Charlies Butte and Whitney Bridge, which can be accounted for by channel evaporation. The water plane of the valley on each side of the river lies between high- and low-water levels in the river. Hence, seepage gain and loss are the result of local ab-

sorption and drainage along the river channel, and have no relation to the general ground-water situation of the basin.

Evaporation and Transpiration.

Evaporation from Water Surfaces.—Measurements of evaporation from free water surfaces were made under three conditions: from a pan floating in a body of water, from a pan placed in the soil, and from a deep tank placed in the soil. The first and second were designed to furnish data regarding evaporation from reservoir surfaces and from areas of shallow flood water, respectively. The third was desired for purposes of comparison with records of evaporation from soil. The pans, which were of the pattern used by the U. S. Reclamation Service, were 3 ft. square and 10 in. deep, and were of galvanized sheet-iron. Observations were made by replacing the quantity evaporated with a cup having a capacity equal to a depth of 0.01 in. in the pan. The initial height of the water surface was such that a pin, projecting from the center of the pan and remaining at a fixed height, 2 in. below the rim, was just submerged. The deep tank was circular, 3½ ft. in diameter and 4 ft. deep, and observations were made in a stilling well with a hook-gauge and vernier scale reading to 0.01 in. The records were all kept near Independence, and observations were made every second day in summer and every fourth day in winter.

The record for the pan in water (Table 6) is available from August 4th, 1908, to June 1st, 1911. The pan, Fig. 3, at first, was in Blackrock Slough, but was moved to its final location, in Owens River at Citrus Bridge, on May 7th, 1909. The pan was supported by a timber float, which protected it from splashing water. The depth of water beneath the pan varied from 1 to 5 ft., depending on the river stage. The river water had a moderate velocity, and varied in temperature from about 75° Fahr., in summer, to about 40° Fahr., in winter. The river banks averaged 4 ft. high above the water surface, and the pan was about 30 ft. from them. Rain gauge No. 18 was 100 ft. away, on the river bank, and was observed in connection with the evaporation record.

The record for the pan in soil is broken. It extends from August 1st, 1909, to November 30th, 1909, and from March 14th, 1910, to June 1st, 1911. The pan, Fig. 4, was in the valley floor at the soil evaporation experiment station, about 3 miles east of Independence.

It was set in a shallow excavation with soil banked up to about half the depth of the pan. Water temperatures range from 95° Fahr., in summer, to 32° Fahr., in winter. The surface temperature was about 1° warmer than that for the mixed contents of the pan. Table 7 summarizes the results by months for this pan, and, by comparing it month by month with the evaporation from the pan in water, an average excess of about 33% is observed. This is probably due to the higher temperature of the water in the pan in soil during the hours of sunlight.

* August 10th to 31st, inclusive.

The deep-tank record extends unbroken from April 16th, 1909, to Dec. 31st, 1911. The tank, Fig. 6, was at the soil evaporation experiment station, and was set in the soil with the upper rim flush with the surface. The water surface was not allowed to fall more than 4 in. below the rim. The temperature of the surface water varied from 80° Fahr., in the heat of summer to freezing in winter. Except during freezing weather, the average temperature of the contents of the tank was 5° less than that of the surface layer. The presence of the surrounding soil makes the range in temperature less than that for the shallow pan. The record, which is presented in Table 8, indicates an annual depth of evaporation practically equal to that from the pan in water at Citrus Bridge. The monthly distribution is more uniform,

there being 70% of the total during the 6 summer months and a difference of 27 in. between summer and winter evaporation. The effect on evaporation of the modified temperature extremes of the soil is well shown by comparison with the record for the pan in water (Table 6). The temperature conditions for the deep tank agree closely with those of the surrounding soil.

Evaporation from Ground Surface.—Water in the surface layers of the ground is subject to evaporation, either directly from the soil or through vegetation by the process of transpiration. It is available for evaporation in Owens Valley under two conditions: temporarily, following a rainstorm or sudden thaw, and permanently, within areas where the average depth to ground-water does not exceed 8 ft. The total evaporation under the first condition is relatively unimportant, because of the infrequency of storms and the small quantity of precipitation, and no attempt was made to measure it. Under the second condition, however, evaporation losses are large, for, not only is soil capillarity able to draw gravity water to the surface, but roots of vegetation, such as wild grass, penetrate the soil to ground-water and become the channels by which a large quantity of moisture is conveyed into the atmosphere. Evaporation from bare soil combined with transpiration is, in fact, the most important element entering into computations relating to ground-water for this region. So few data are available on the subject that extended observations were undertaken.

Owens Valley is an ideal location for carrying on such experiments. In the first place, the source of water available for evaporation may be kept under the complete control of the observer as regards the quantity and rate of supply. Storms are rare, and the total precipitation is small, so that little uncertainty exists from this cause regarding the quantity of percolation from precipitation on the surface of a body of isolated soil. Second, the method by which the surface soils of the valley floor are kept moist can be reproduced artificially on a small scale with only a slight departure from natural conditions. The source of supply for soil moisture is a permanent ground-water surface from which water is drawn by capillary forces. This ground-water is replenished by percolation from the precipitation and surface water of the intermediate mountain and outwash slopes, which seeps laterally toward the valley floor and lies beneath it under hydrostatic pressure sufficient to maintain a permanent ground-water surface.

FIG. 6.—DEEP-WATER EVAPORATION TANK.

FIG. 7.—SOIL TANK NO. 3 IN OPERATION.

Similar pressure can be reproduced in the bottom layer of an isolated body of soil, and capillary forces can be depended on to raise moisture to the surface. Finally, the large annual depth of evaporation makes possible a more accurate determination of its quantity than in a less arid region. Experiments carried on under these conditions have been very satisfactory.

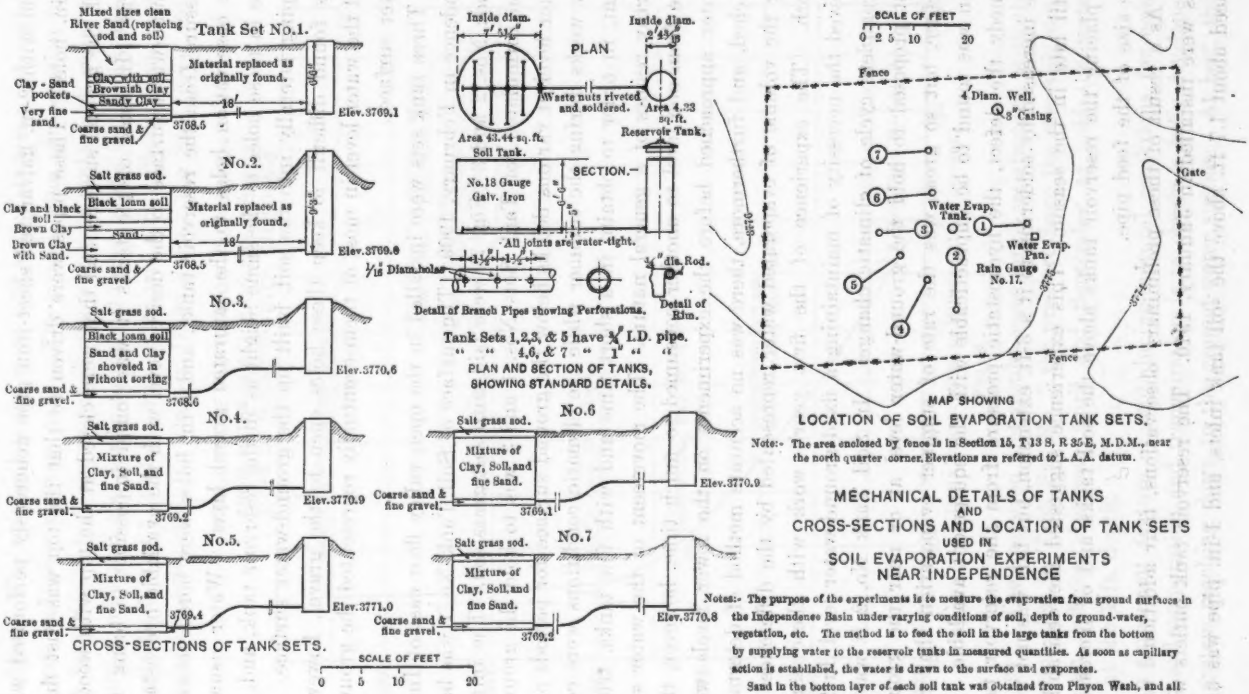
The rate of evaporation from soil depends on the temperature of the air and soil, the quantity of moisture already in the immediately surrounding atmosphere, the quantity of moisture in the surface layers of the soil, and the character of the vegetation and other soil covering. The first two of these factors have the same effect on soil evaporation as on that from a free water surface—higher air and soil temperatures result in increased evaporation, as does also dryer atmosphere or increased movement of wind. The third factor is directly proportional to the rate of evaporation, because the loss of moisture occurs from soil grains at or very near the surface. The quantity of moisture in the soil available for evaporation thus depends on the character of the soil, as regards capillarity and depth to the ground-water surface. For example, in a coarse, sandy soil, "gravity water" will be drawn to the surface through the capillary spaces from depths not exceeding 4 ft., and, in a fine sandy or clayey soil, water will be drawn from depths as great as 8 ft. The last factor, the extent and character of vegetation, affects the evaporation rate both through the activity of transpiration and the effect on capillarity. Plant roots are continually absorbing water from the soil; this water passes off into the atmosphere through the leaves, and the evaporation losses from soil are greatly increased thereby. The roots of native salt grass will penetrate to a depth of 8 ft. in search of water. A further effect of the growth of vegetation is to increase the vertical capillary flow of moisture through soil by way of the many tubes filled with the rotted fiber of dead roots. These tubes are the result of years of growth, and penetrate the soil in all directions above the ground-water surface.

The purpose of the experiments was to obtain data sufficiently complete to compute the total volume of water annually lost by evaporation and transpiration from the valley floor. This involved making observations under the various local conditions which affect soil evaporation. The plan was to reproduce natural conditions in isolated bodies of typical soil and determine the evaporation therefrom for

varying climatic conditions, depths to ground-water, soils, and vegetation.

The experimental equipment consists of two galvanized-iron tanks, 6½ ft. in depth, connected at the bottom by an 18-ft. length of galvanized pipe. (See Fig. 8.) The smaller tank is 2 ft. $4\frac{3}{16}$ in. in diameter, and has a tight-fitting cover. The larger tank is 7 ft. 5¼ in. in diameter, and has a system of branching perforated pipes at the bottom connected with the pipe from the smaller tank. The two tanks and all connections are water-tight, and water poured into the smaller or reservoir tank passes into the larger or soil tank and escapes through the perforations. These two tanks were placed in excavations of proper size to receive them, the soil tank was filled with the excavated soil, and the reservoir tank was filled with water. A 6-in. layer of screened gravel, too coarse to enter the $\frac{1}{16}$-in. perforations, was laid in the bottom of the soil tank in order to insure an uninterrupted and well-distributed feeding of water from the reservoir tank into the superimposed soil. As soon as the material became saturated and capillary action was established to the surface, the water level in the soil was brought to the desired depth and kept there by supplying water to the reservoir tank in measured quantities. Volumetric measurements of water poured into or withdrawn from the reservoir tanks were made with an ordinary gallon measure. Accumulation or depletion of the supply in the reservoir tank was determined volumetrically by measuring the depth of water with a steel tape. The volume passing out of the reservoir tank during a given period represents the total evaporation from the soil tank during that period.

The position of the ground-water surface in the soil tank was determined by measuring its depth below the ground surface in 2-in. augur holes bored in the soil to a proper depth. Measurements were made from a fixed point with a steel tape weighted at the end and chalked before each observation. Three holes were placed in each tank, half way between the center and rim, on radii 120° apart. The holes were not bored deep enough to reach the bottom layer of coarse gravel, and the water level in them represented the ground-water surface in the surrounding soil. An average of the observations made at a given time was assumed to represent the general depth to ground-water for the tank at that time. The tendency of the sides of the holes to cave in and the bottom to fill with sand was controlled by casing



Note:- The area enclosed by fence is in Section 15, T 13 S, R 35 E, M.D.M., near the north quarter corner. Elevations are referred to L.A.A. datum.

MECHANICAL DETAILS OF TANKS AND CROSS-SECTIONS AND LOCATION OF TANK SETS USED IN SOIL EVAPORATION EXPERIMENTS NEAR INDEPENDENCE

Notes:- The purpose of the experiments is to measure the evaporation from ground surface in the Independence Basin under varying conditions of soil, depth to ground-water, vegetation, etc. The method is to feed the soil in the large tanks from the bottom by supplying water to the reservoir tanks in measured quantities. As soon as capillary action is established, the water is drawn to the surface and evaporates.

Sand in the bottom layer of each soil tank was obtained from Pinyon Wash, and all sizes less than 1/16" were screened out.

FIG. 8.

them with 2-in. galvanized sheet-iron pipe generously perforated with $\frac{1}{16}$-in. holes. These pipes were driven so that the top was just flush with the ground surface, and they were closed at the top with wooden plugs. In some of the tanks it was found impossible to bring the ground-water surface to the desired level with the available hydrostatic pressure from the reservoir tanks, and 2-in. holes were bored between the observation holes to the saturated gravel layer. Water usually rose in these holes to the same height as in the reservoir tank, and, by seeping laterally into the soil, built up the ground-water surface. It was found difficult to keep these holes open to the gravel, however, and the water level in most of them eventually represented the ground-water surface.

Three tank sets were installed in the open valley floor east of Independence in February, 1909. The surface of Soil Tank No. 1 was bare sand; Nos. 2 and 3 (Fig. 7) were laid with salt-grass sod. The initial plan formulated for Tank Sets Nos. 1 and 3 was to hold the ground-water level at various depths below the ground surface for periods of a few weeks during the summer while the climatic conditions were constant, in order to obtain, in a short time and with few tanks, trustworthy results of a general nature. The movement of the water surface from one level to another consumed so much time, however, that winter approached before the experiments on the lower levels were reached, and furthermore, there was no accurate method of determining the volume of evaporated water represented by the differences in depth. The experience of the first year's work with these tanks showed the necessity of maintaining a fixed ground-water level during a complete cycle of climatic changes. In Soil Tank No. 2 it was at first proposed to hold the ground-water level at or near the ground surface, but so great was the rate of summer evaporation that this plan was found to be impracticable with the equipment available. To remedy the defect, the hydrostatic pressure from the reservoir tank was increased by soldering to it a 3-ft. extension, but this was not used until late in the season. This experience suggested the desirability of placing the reservoir tanks above the soil tanks and of increasing the size of the feed pipe.

As a result of these preliminary observations, four additional tank sets were installed in January, 1910. The reservoir tank outlets were placed about 1.7 ft. above the soil tank inlets, and 1-in. pipe was used

throughout. The new soil tanks were laid with salt-grass sod, which took root and grew in every tank. The general plan of operation for Tank Sets Nos. 2 to 7 was to supply the reservoir tanks with water in quantities such that the depths to ground-water in the soil tanks were, respectively, 5 ft., 4.5 ft., 4 ft., 3 ft., 2 ft., and 1 ft. Observations were carried on continuously on the six tanks during the two years, 1910

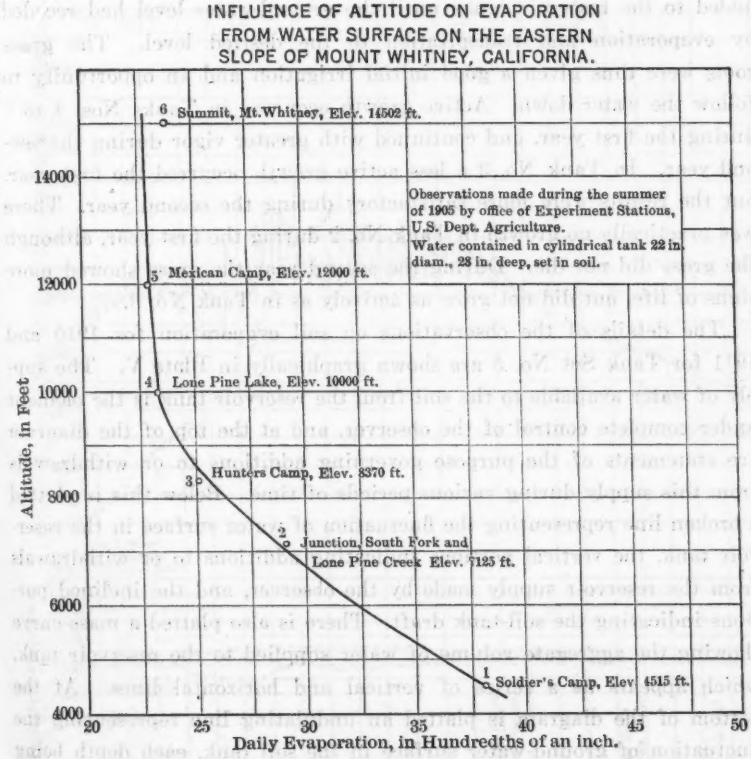


FIG. 9.

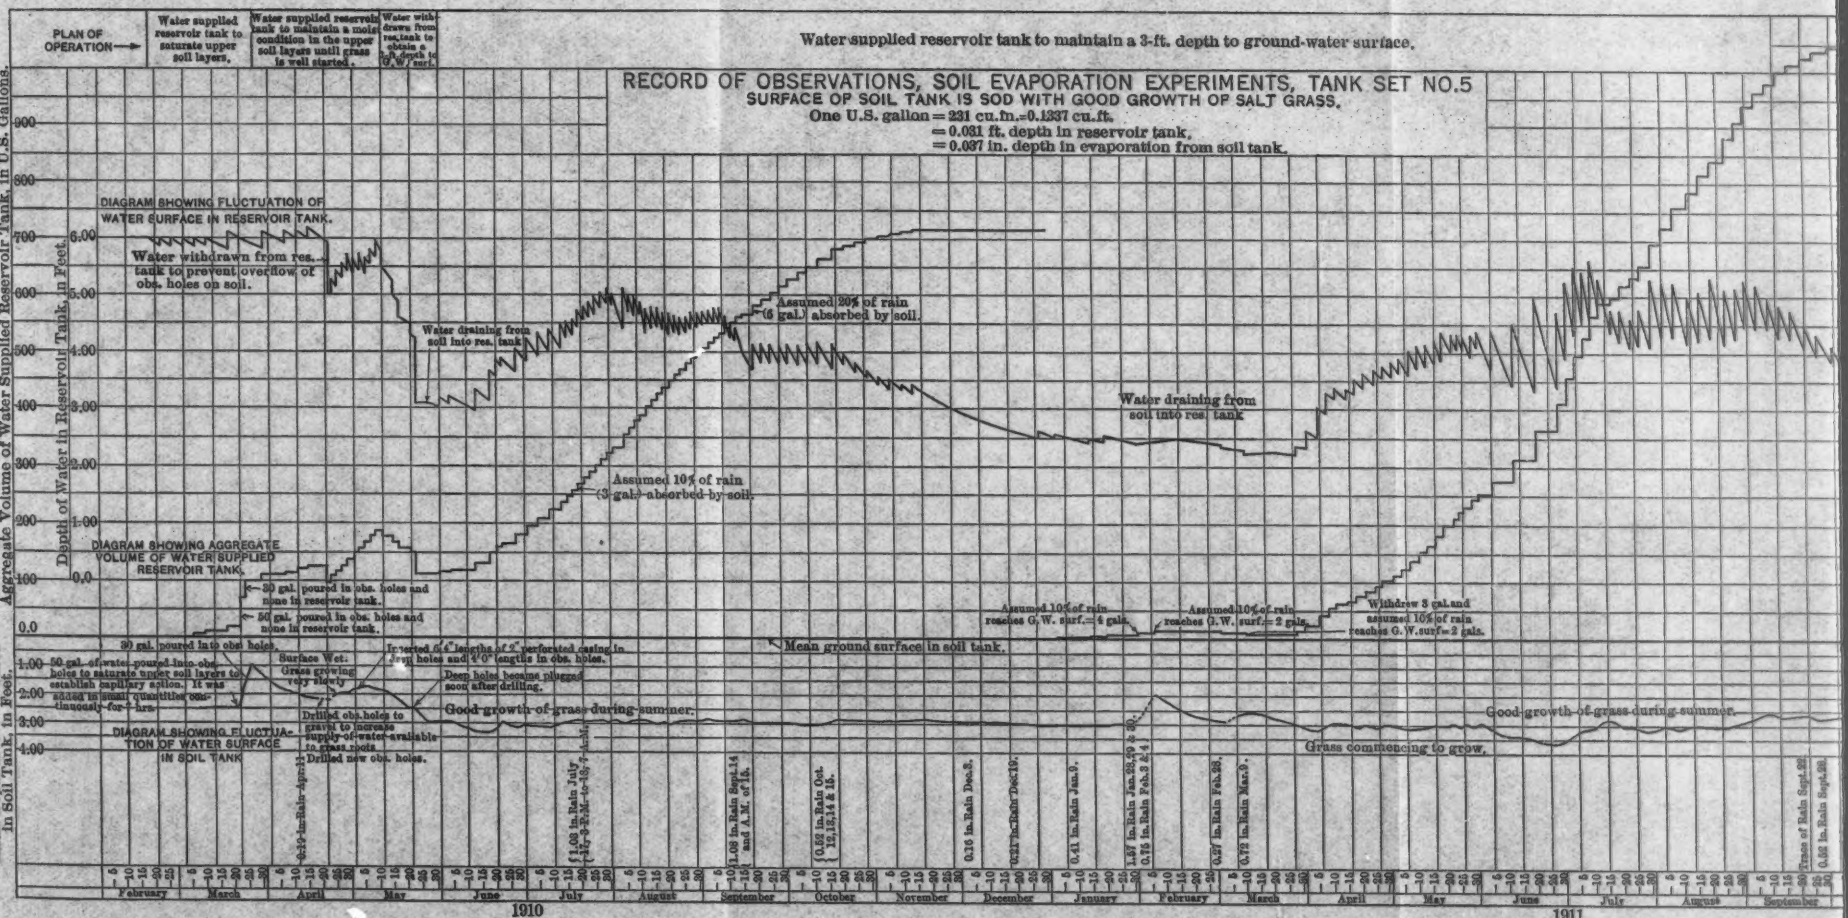
and 1911. The operation and results were quite satisfactory, with the exception that in Tank Set No. 7 the pressure from the reservoir tank was not sufficient between April and September to hold the water level at the 1-ft. depth.

An important feature of reproducing natural conditions for combined soil evaporation and transpiration is to obtain a fully developed root system reaching down to the ground-water surface. At best, this

requires more than a year, particularly for the greater depths. In order to stimulate the growth as much as possible, the water level in all soil tanks was brought up to about 1 ft. below the surface as soon after installation as possible. This was accomplished by pouring water into the observation holes until the soil was completely saturated to the level desired and the surface showed moisture. Then no water was added to the reservoir tanks until the ground-water level had receded by evaporation and transpiration to the desired level. The grass roots were thus given a good initial irrigation and an opportunity to follow the water down. Active growth occurred in Tanks Nos. 4 to 7 during the first year, and continued with greater vigor during the second year. In Tank No. 3 a less active growth occurred the first year, but the results were more satisfactory during the second year. There was practically no growth in Tank No. 2 during the first year, although the grass did not die. During the second year the grass showed more signs of life, but did not grow as actively as in Tank No. 3.

The details of the observations on soil evaporation for 1910 and 1911 for Tank Set No. 5 are shown graphically in Plate V. The supply of water available to the soil from the reservoir tank is the element under complete control of the observer, and at the top of the diagram are statements of the purpose governing additions to or withdrawals from this supply during various periods of time. Below this is platted a broken line representing the fluctuation of water surface in the reservoir tank, the vertical portions indicating additions to or withdrawals from the reservoir supply made by the observer, and the inclined portions indicating the soil-tank draft. There is also platted a mass-curve showing the aggregate volume of water supplied to the reservoir tank, which appears as a series of vertical and horizontal lines. At the bottom of the diagram is platted an undulating line representing the fluctuation of ground-water surface in the soil tank, each depth being obtained by averaging the depths recorded in the observation holes.

The small part that precipitation plays in ground-water fluctuations in Owens Valley is shown by this diagram. The average annual precipitation at the experiment station is about 4.38 in., the season, 1909-10, being normal and 1910-11 well above normal. At the bottom of the diagram is noted the date and quantity of precipitation for each storm. It is seen that, even in a wet season, percolating water does not penetrate to depths exceeding 2.5 ft., unless more than 1 in. falls



PLAN OF OPERATION
Water supplied reservoir tank to saturate upper soil layers.
Water supplied reservoir tank to maintain a moist condition in the upper soil layers until grass is well started.
Water withdrawn from res. tank to obtain a 3-ft. depth to G.W. surf.

UNIV. OF

within a short period on moist soil. Even then it does not appear to reach depths greater than 4 ft. The problem of percolation from rainfall, therefore, is practically eliminated from the experiments. When rising ground-water was noted in a soil tank after precipitation, the volume of percolating water was estimated from the observed rise and included in the mass-curve, as noted on the diagrams.

The quantity of water evaporated from the soil surface of any tank during a given period can be computed accurately from the diagrams, when the depth to ground-water at the beginning and end of the period is the same, by noting from the mass-curve the quantity supplied to the reservoir tank during the period and the accumulation or depletion in the reservoir tank. The sum of these quantities, with their proper algebraic sign, gives the loss by evaporation. For differing depths to ground-water, however, the computations are only approximate, because the proportion of empty space in the soil layer and the quantity of moisture it contained initially are both unknown. A monthly summary of results for Tank Sets Nos. 2 to 7 for 1911 is presented in Tables 9 to 14. The annual depth of evaporation from the several soil tanks exhibited a consistent decrease with increase of depth to ground-water, and varied from 48.8 in. for No. 7 to 13.43

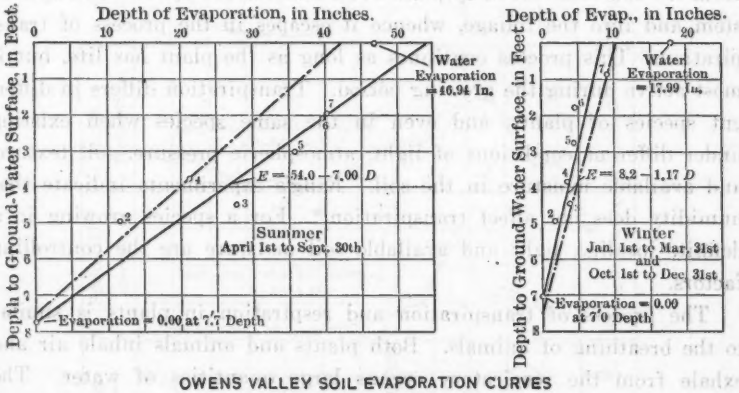
in. for No. 2. The depth of summer evaporation varied from 81 to 90% of the annual in the several tanks, and averaged 87 per cent. The month of maximum evaporation is August, and minimum evaporation occurs during December to March, inclusive. The exact date of maximum evaporation rates for the several soil tanks occurs about September 1st, and they follow each other consecutively with greater depth to ground-water. The approximate dates of maximum and minimum air temperatures at Independence are July 10th and January 10th, respectively, but no measurements were made to determine the lag of corresponding soil temperatures at various depths. The extremes of evaporation from water surfaces agree in time of occurrence with maximum and minimum air temperatures, however, and the observed lag in soil evaporation is in general consistent with the observed lag in soil temperatures in other localities. Hence it is reasonable to conclude that extremes in the rate of soil evaporation and soil temperature are concurrent at a given depth.

A graphic study of the data in Tables 9 and 14 for the periods, April 1st to September 30th, and October 1st to March 31st, which are, respectively, periods of increasing and decreasing evaporation rate, is presented in Fig. 10. There appears to be, during each period,

a straight-line relation between total evaporation and depth to ground-water. The limiting depth is 7.7 ft., and the total evaporation when water and ground surface coincide, 54.0 and 8.2 in., respectively. The total depth of evaporation, in inches, being represented by E, and the depth to ground-water, in feet, by D, the equations representing variation in evaporation with depth to ground-water are $E = 54.0 - 7.00\ D$ and $E = 8.2 - 1.17\ D$. It will be noted that the combined soil evaporation and transpiration during the summer exceeded the water evaporation from the tanks in the soil by 15 per cent.



OWENS VALLEY SOIL EVAPORATION CURVES
FOR ALKALI SALT GRASS LAND
Based on Soil Tank Observations of 1911.
——— Curve based on 1911 Data.
– – – – Curve based on 1910-11 Data.
o 1911 Observations.

FIG. 10.

The curve based on the 1910-11 data is shown on the diagram for comparison. There was a marked increase in total evaporation during 1911, as compared with the season, 1910-11, which was due to the more complete development of the root systems. Broadly speaking, the results for 1911 showed an increase of 17% in the volume of water consumed during the two periods. A continuation of observations for another year would show still further increase for those tanks in which the grass roots had not reached the water plane. Observations of depth to water in test holes in the transition zone between meadow and desert land indicate that soil evaporation ceases for depths exceeding 8 ft. The effect of increased evaporation for the tanks with greatest depth to ground-water would be to drop the lower end of the

curve to some point below 7.7 ft. The true curve, therefore, is probably steeper than that for 1911, crossing the X-axis at about the same point, but the Y-axis at about 8 ft. instead of 7.7 ft. However, in the practical use of the curve, the departure of the lower end from the true position does not affect materially the computations of the total volume of water evaporating from a given area, as the proportion of such volume originating in areas of relatively deep ground-water is small.

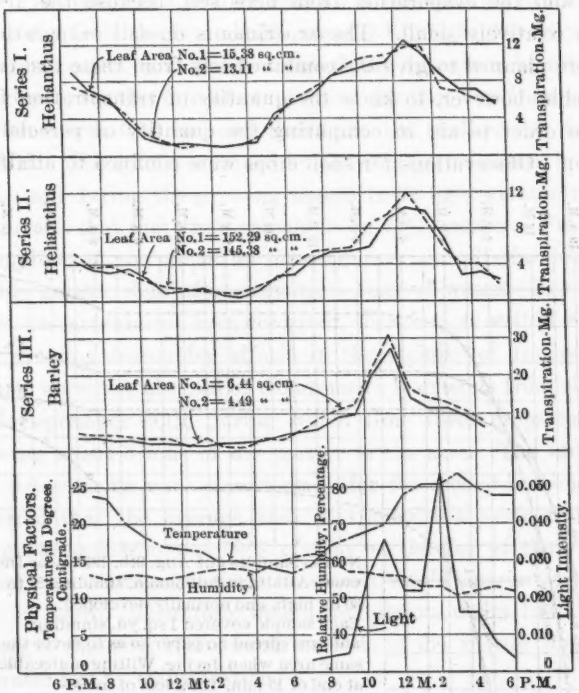
Transpiration.—A considerable portion of the water evaporating from the soil is absorbed by plant roots and carried upward through the stem and into the foliage, whence it escapes in the process of transpiration. This process continues as long as the plant has life, but is most active during the growing period. Transpiration differs in different species of plants, and even in the same species when existing under different conditions of light, atmospheric pressure, soil texture, and available moisture in the soil. King's experiments indicate that humidity does not affect transpiration.* For a species growing in a definite locality, light and available soil moisture are the controlling factors.

The process of transpiration and respiration in plants is similar to the breathing of animals. Both plants and animals inhale air and exhale from the respiratory organs large quantities of water. The lungs of animals are intended primarily to provide a means for the entrance of oxygen into the body and for the escape of carbon dioxide, but they cannot perform their functions unless the interior lining of the air cells is kept moist. Similarly, the breathing surface of a plant must be kept moist, and, as a protection from too rapid evaporation, this surface is within the plant structure, principally in the foliage. Plant leaves are enclosed in a relatively impervious skin or epidermis in which are small breathing pores or stomata which open or close automatically, depending on the needs of the plant for a greater or less quantity of air. When exposed to light, the food-manufacturing processes of a green plant are stimulated, and require a continually changing volume of air in contact with the breathing surface. The stomata open proportionally to the light intensity. Should the water supply in contact with the roots be insufficient, the breathing surface may become dry, and when that happens the stomata close automatically

* "Irrigation and Drainage," by F. H. King, New York, 1899.

until the proper quantity of air is admitted for the plant to do its work under the new conditions. The stomata, therefore, control the quantity and rate of loss of water from plants by transpiration.

There is a marked diurnal periodicity in the rate of transpiration, which investigators are led to believe is largely the result of the varying intensity of light. This periodicity is well illustrated by ob-



RELATION OF TRANSPIRATION TO LIGHT INTENSITY DURING A 24-HOUR DAY.

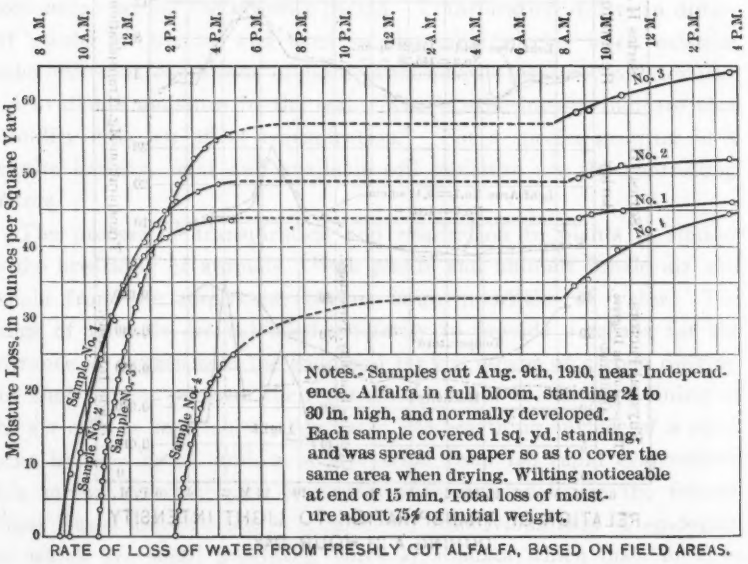
FIG. 11.

servations made under the direction of Mr. Frederick E. Clements, State Botanist of Minnesota, and reproduced in Fig. 11.* Measurements of transpiration were made hourly from 6 P. M. on February 16th to 6 P. M. on February 17th, and the physical factors were observed between these hours. The day was cloudy throughout, so that

* "Influence of Physical Factors on Transpiration", by A. W. Sampson and L. M. Allen, Minnesota Bot. Studies, Pt. I, Vol. 4, 1909, p. 42.

the variation in temperature and humidity was slight. The diagrams show very strikingly the response of transpiration to changes in intensity of light.

No measurements of transpiration are available for conditions similar as regards altitude and aridity to those in Owens Valley. It is unnecessary in this study to know separately the transpiration from wild grasses and the evaporation from bare soil, because the area of the latter is relatively small. The experiments on soil evaporation, therefore, were planned to give the combined loss from these two causes. It is desirable, however, to know the quantity of transpiration from field crops, in order to aid in computing the quantity of percolation from irrigation. Observations for such crops were confined to alfalfa.



RATE OF LOSS OF WATER FROM FRESHLY CUT ALFALFA, BASED ON FIELD AREAS.

FIG. 12.

The method of measurement was based on the assumption that the rate of loss of water from freshly cut plants would correspond closely to the rate before cutting. The plants were cut rapidly from a measured area, weighed, and spread out on paper to cover the same area as before cutting. At short intervals they were reweighed until there was no further appreciable loss. No noticeable wilting occurred during the first 15 min. and the rate of loss during this period was used as

a basis for calculations. The results of the measurements are shown graphically in Fig. 12.

The rapid decrease in the rate of loss is very noticeable. Inspection of Fig. 11 will show that the rates of transpiration at 8.45, 9.15, and 10.30 A. M., and 2.02 P. M., expressed as percentages of the average rate for 24 hours, are, respectively, 128, 141, 177, and 197, an average of 161 per cent. If a similar relation is assumed, the average loss in a 24-hour day from the four alfalfa samples would be 366 oz. per sq. yd. of field area, or 0.49 in. in depth. This figure appears to be rather large, at first glance, for the rate of evaporation for that day from the pan in Owens River was 0.30 in., and that from the shallow pan in the soil was 0.38 in. The results obtained by German investigators indicate the loss from sod during the growing season to be 92% greater than from water surface, and that from cereals to be 73% greater. Furthermore, the humidity of the air after passing over an alfalfa field is very noticeably greater than after crossing a body of water. The result obtained in the experiment here described, therefore, is within reason.

The growing season for alfalfa in the vicinity of Independence is marked by an entire absence of cloudiness. It extends from about April 15th to September 30th, during which time three crops mature, the yield being about 5 tons of dry matter to the acre. The samples used for the experiments were almost ready for the second cutting. On the assumption that the average area of transpiring surface during the entire growing season was 50% of that on the day of the experiment, the total loss of water during the season would amount to 41 in., or 3.43 ft. in depth. Therefore, with a production of dry hay, amounting to 5 tons to the acre, there would be 1 lb. of dry matter for every 93.5 lb. of water lost by transpiration.

Ground-Water.

Form of the Ground-Water Surface.—The general form of the ground-water surface corresponds with that of the surface of the valley fill, although the slopes are less steep and the irregularities are not so pronounced. In the valley floor the depth to ground-water is only a few feet. It becomes progressively greater toward the mountains, and probably lies 200 or 300 ft. beneath the outwash slope at about the 5 000-ft. contour. Superimposed on the general ground-water surface are sharp "ridges" beneath stream channels and "mounds" under irrigated

fields. The surface of the water in the underground reservoir, therefore, is not a level plain, but has a varied topography.

There are two reasons for this condition: the action of gravity tending to equalize inequalities in the ground-water surface, and the resistance which the ground offers to the lateral motion of water through its interstices. Percolating waters enter the valley fill from the upper edge of the outwash slope, from stream channels crossing the outwash slope, and from irrigated fields. The valley floor is the lowest portion of the valley fill and also the ground-water outlet. The force of gravity, therefore, tends to draw percolating water which has reached the surface saturation to the level of the valley floor. This can occur only by a lateral movement of water from the outwash slope toward the valley floor, but the resistance of the porous material is so great that a steep gradient is necessary to maintain even a very low velocity. Hence there is the steep slope of the ground-water surface from the mountains toward the valley, at many points exceeding 80 ft. per mile, and laterally from stream channels and irrigated fields. The lateral movement of the water is so slow that percolating water entering at the upper edge of the outwash slopes, does not reach the valley for at least 2 years.

In order to outline the ground-water definitely, all existing domestic wells in the region were located and many additional observation wells were drilled, where the cost was not prohibitive. The region contains 27 domestic wells, 12 of which are on the valley floor and 15 on the outwash slopes. There were drilled in addition 142 observation wells, all but two being on the valley floor. These wells were sufficient to define the ground-water surface over about 60 sq. miles of the region.

Ground-water contours for the valley floor showing lines of equal average depth to ground-water have been worked out on Plate VI. They represent the average position of the surface of saturation between the annual extremes. The data are sufficient to determine the 3-, 4-, and 8-ft. contours with reasonable accuracy. The sudden approach of ground-water toward the surface at the upper edge of the grass land is shown, and also the general proximity of ground-water to the surface throughout the valley floor. The total area between the westerly 8-ft. contour and Owens River is 67 sq. miles. The average depth to ground-water is between 4 and 8 ft. over 40% of this area, and between 3 and 4 ft. over 28 per cent. It exceeds 8 ft. over 14% of the area, and is 3 ft. or less over 18 per cent. The area of the valley floor is 66.4 sq. miles

(Table 1), and its west boundary practically coincides with the 8-ft. contour.

There is a very striking relation between vegetation and depth to ground-water. On the outwash slopes the vegetation consists of various stunted desert shrubs. In approaching the valley floor at about the 20-ft. contour, sagebrush begins to predominate, and has a luxuriant growth as far east as the 12-ft. contour, where it is replaced by greasewood, rabbit brush, and coarse bunch grass. In the vicinity of the 8-ft. contour, salt grass begins to appear, and farther east, near and within the area inclosed by the 4-ft. contour, it grows luxuriantly. Within the 3-ft. contour, fresh-water grasses thrive where there is sufficient surface water to leach out and carry away most of the alkali, but the salt grass grows well, even where the soil is alkaline. In various portions of the valley floor rabbit brush and greasewood are found where the average depth to ground-water is 4 ft. or more, but grass predominates east of the 8-ft. contour. In areas where the alkali is excessive there is practically no vegetation. In general, grass does not grow where the depth to ground-water exceeds 8 ft., so the 8-ft. contour tends to coincide with the boundaries between meadow and desert lands.

Fluctuation of the Ground-Water Surface.—The surface of the ground-water is continually fluctuating. Both the extent and character of this fluctuation vary widely in different localities and at different times, depending on the proximity to ground-water sources or outlets and the relative rates of ground-water accretion and depletion. Three pronounced types are to be observed in the Independence Basin: (1) broad irregular fluctuations of varying amplitude in the outwash-slope area; (2) slightly irregular periodic fluctuation with wide fixed limits in and near irrigated areas; and (3) a regular periodic fluctuation with comparatively narrow and fixed limits in the valley floor. Special characteristics are also exhibited by wells within certain limited areas, as the result of local ground-water conditions.

These fluctuations were determined and studied from well observations made by the methods already described. Readings obtained at intervals of from 2 to 4 weeks were sufficient to establish accurately the position of the ground-water surface, as the fluctuations are characterized by great regularity. Most of the wells were observed from August 15th, 1908, to November 15th, 1909, and on 26 of the most

typical wells observations were continued to May 1st, 1911. The fluctuation of the surface of the lake south of Citrus Bridge was observed from August 15th, 1908, to November 15th, 1909, and of Goose Lake from August 15th, 1908, to May 1st, 1911.

The type of fluctuation peculiar to wells on the outwash slope is shown in Plate VII by Wells Nos. 31, 64, 25, 26, and 59, and Citrus No. 1. Water stands 10 ft. or more below the surface in all these wells, the vegetation of the surrounding area is limited to desert shrubs, and there are no alkali deposits on the surface. With knowledge of the sources and movements of ground-water beneath the outwash slopes, the assigned cause for this type would be annual variation in the quantity of water supplied by percolation from precipitation on the intermediate and outwash slopes and from stream channels. This is confirmed by the observations. For example, Well No. 31, which is 7 miles from the base of the Sierra and 500 ft. south of the old channel of Pinyon Creek, exhibits a persistent downward tendency which was partly checked during the summer of 1909 and 1910. The maximum effect of the very wet years, 1906 and 1907, evidently reached this well in 1908 and early in 1909. During the following years the water had a tendency to return to its normal level. This was twice opposed by percolation from the channel of Pinyon Creek, which carried flood-water during a few weeks in June and July, 1909, and for a very short period in 1910. Citrus Well No. 1, which is about $\frac{3}{4}$-mile south of Well No. 31, has similar fluctuations, but in it the maximum effect of seepage from Pinyon Creek is registered 6 weeks later in 1909, and in 1910 is much smaller in quantity. Well No. 64, situated similarly with respect to the mountains, but north of Little Pine Creek, has the same downward tendency, which is checked temporarily during the summer by irrigation in a near-by alfalfa field and a small garden at the well. Well No. 59, which is 2 miles from the base of the Sierra and $\frac{1}{2}$ mile south of Sawmill Creek, had an upward tendency during 1909, due to the percolation from precipitation of the wet winter, 1908-09. In 1910 the water level fell in response to the normal winter of 1909-10. Seepage from Sawmill Creek does not affect this well appreciably. Wells Nos. 25 and 26 exhibit the general tendencies of Well No. 59, but they are in the transition zone between the outwash slope and the valley floor, where there is a periodic back-water effect from the annual rise of ground-water in the grass land.

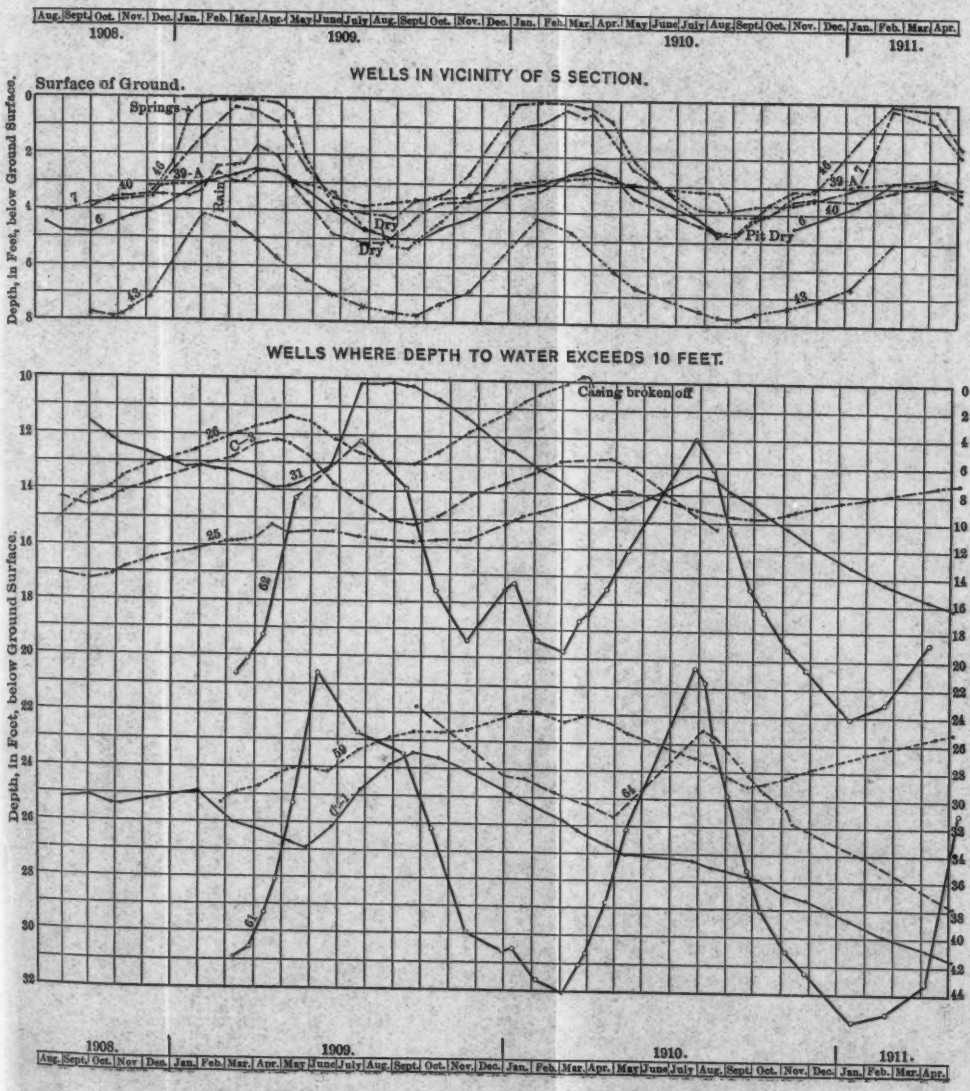
WELLS IN INDEPENDENCE BASIN



UNIV. OF MICH.

Wells Nos. 61 and 62 illustrate the type of fluctuation characteristic of the irrigated areas of the region. They are in irrigated gardens in the Town of Independence. The form of the curve is periodic, with sharp crests and troughs, the former in July, the latter in January or February. The fluctuation in such wells ranges from 10 to 20 ft. in different portions of the basin. Irregularities superimposed on the broad periodic curve are the result of irregularity in the application of irrigation water.

The fluctuation of the ground-water surface in various parts of the valley floor, other than at the eight wells already mentioned, is shown by 48 typical well records on Plate VII.

Permanent bench-marks were established at each well, and test holes from which measurements to the water surface could easily be made with a steel tape. Before observing, a weight is fastened at the end and the tape is chalked. The end of the tape is then submerged and the difference between the readings at the bench and at the water surface is the depth. Corrections are made in the office when the bench is not at the ground surface. Readings are to feet and hundredths.

Most of these wells are where the average depth to ground-water is less than 8 ft. The adjoining ground surface is more or less crusted with alkali, and, where the alkali is not too concentrated, several species of wild grass grow vigorously. The two lakes and Wells Nos. C-3 and 43 are in areas where the average depth to ground-water exceeds 8 ft., and desert conditions prevail.

The fluctuations observed in all the valley-floor wells are remarkably uniform. When platted, the observations give smooth and regular curves with an annual periodicity. The average time of occurrence of crests for wells in grass or alkali areas is March 28th; the troughs occur on September 20th, 6 months later. Heavy winter precipitation, or the proximity of springs, advances the crests into January or February, but, in the desert areas, the crest lags into April or May. The fluctuation between maximum and minimum levels in normally situated wells ranges from 1.5 to 4 ft. Wells which are near or below springs in the vicinity of intermittently occurring surface water have a greater range, which may reach 7 ft. The average fluctuation for 1908-09, as observed in 122 wells distributed generally over the valley floor, is 3.14 ft. This average represents normal conditions.

Fluctuation of this type is due to evaporation from the soil and transpiration, processes which are active wherever there is capillary connection between the surface of saturation and the ground surface, or wherever gravity water or capillary water is within reach of plant roots. Two facts have led to this conclusion: (1) the area characterized by capillary connection between ground-water surface and ground surface and by accessibility of ground-water to plant roots is coincident with the area exhibiting this type of periodic fluctuation; and (2) the combined rates of evaporation from soil and transpiration, as observed experimentally, increase and decrease concurrently and in the same ratio with the fall and rise of the ground-water surface.

The first of these facts is indicated by the following observations: Surface incrustations of alkali are now known among investigators to be an indication of evaporation from the soil, and a growth of natural grasses certainly shows the presence of water within reach of plant roots. These manifestations are both strictly confined to valley-floor areas within which the periodic fluctuation is observed. There are valley-floor areas, however, within which the periodic fluctuation occurs, but which have a loose sandy surface devoid of alkali and vegetation. An examination of such areas shows that they are surrounded or bordered by meadow and alkali-crusted land, and further that maximum and minimum ground-water levels exhibit a lag in time of occurrence which varies with the distance from these adjoining lands. (See Plate VII, Well C-3 and Goose Lake.) The fluctuations in these desert areas do not originate within the areas themselves but in the near-by lands, from which they are propagated as annual waves. In general, average depths to ground-water exceed 8 ft. in desert areas but are less than 8 ft. in meadow or alkali lands.

The second fact—that variations of soil evaporation and transpiration are similar to ground-water fluctuations—is indicated by the results of the experiments on evaporation from soil. The maximum rate of soil evaporation occurs about September 1st and the minimum from December 1st to April 1st. The lowest ground-water level occurs about September 20th and the highest level on March 28th (Plate VIII). Thus the critical points in the curves of soil evaporation and ground-water fluctuation are practically coincident as regards time. Furthermore, although the curves are inversely related, their form is remarkably similar. The obvious conclusion is that ground-water fluctuations

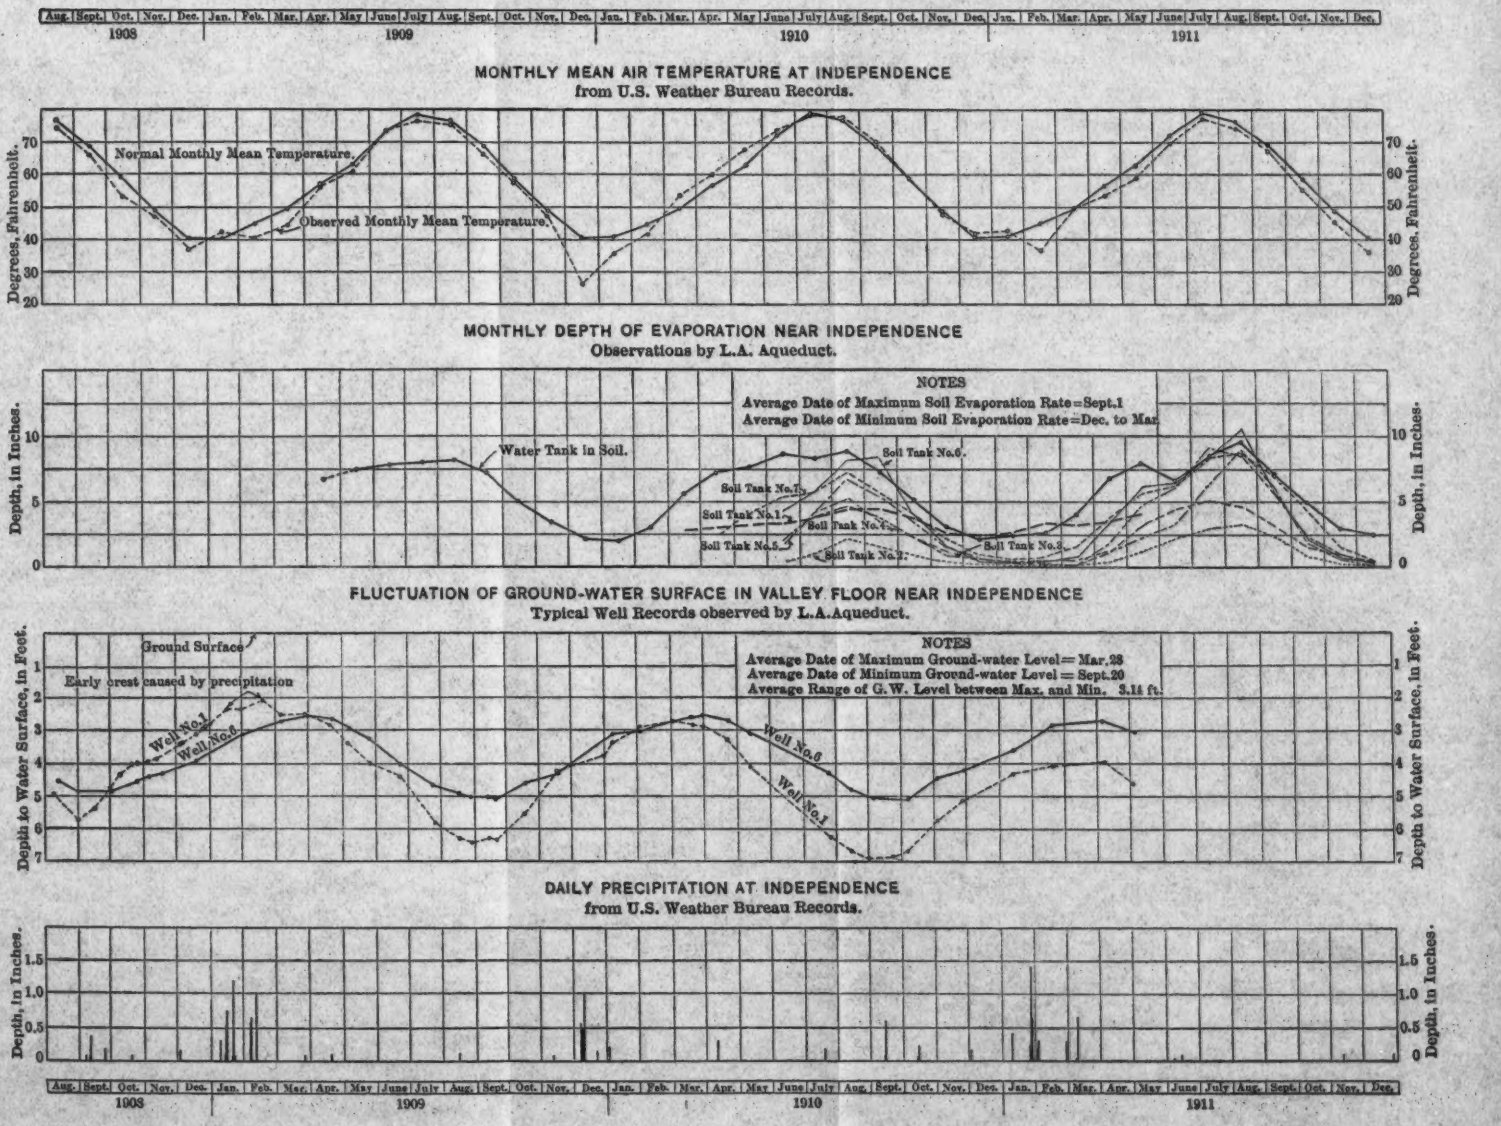
TEMPERATURE, EVAPORATION FROM SOIL, PRECIPITATION AND FLUCTUATION OF GROUND-WATER SURFACE IN VALLEY FLOOR NEAR INDEPENDENCE.



in non-irrigated portions of the valley fill are the result of evaporation from the soil and transpiration.

Variations from the normal periodic curves occur for three causes: large precipitation, seepage from springs, and seepage from standing or flowing surface water. The infrequency of precipitation sufficient to raise the ground-water surface is shown on Plates VII and VIII. It is practically a negligible factor in ground-water fluctuations. The springs at the upper edge of the outwash slope affect ground-water conditions in their vicinity by stimulating the annual rise and maintaining the ground-water level at a maximum during several months prior to March. (See Plate VII, Wells Nos. 46, U-6A, and I-4.) This results from the decrease in the rate of soil evaporation which allows the accumulation of their discharge in the surrounding soil at a greater rate than in adjoining areas where the rate of supply of underground water is less. Surface water has its source in large springs, waste from irrigation, and the flood waters of mountain streams. It occurs at various times and places, and cannot be considered as a permanent factor in ground-water fluctuations. (See Plate VII, Wells Nos. 4, 38, 39-A, 32, and GL-1.) The irregular fluctuations of ground-water on the outwash slope do not appear in the valley floor because of the relief afforded by the escape of water in springs at the upper edge of the grass land.

Ground-Water Losses.—Ground-water fluctuations within the valley floor consist primarily of the regular annual rise and fall produced by variation in the rate of evaporation. This is indicated by actual observations extending over 3 years, and confirmed by the persistency of various perennial plant species. Hence there must be overflow of ground-water from the valley fill of the region equal to the average inflow by percolation. The possible outlets would seem to be underflow southward through the valley fill, underflow by way of deep fissures, seepage and spring flow into the channel of Owens River, evaporation from spring waters, evaporation from damp soil, and transpiration from vegetation. The first two of these are eliminated by the geology and topography of the region. The slope of the ground-water surface in the valley fill opposite the Alabama Hills does not exceed 8 ft. to the mile, and the material is fine sand and clay, as indicated by the Southern Pacific Company's well at Lone Pine Station. Even if there is a movement of ground-water southward from the

region, it must be exceedingly slow, and it would be entirely intercepted by the alluvial fan of Lone Pine Creek, which has a ground-water surface higher than the valley fill to the north. The granitic formation of the Sierra Nevada and the granite core of the Inyo Mountains are complete barriers against the escape of underground waters through any formation but the valley fill. It has already been shown that there is no seepage flow into Owens River from the water supply of the region. Hence the outlets by evaporation, transpiration, and spring discharge into Owens River are all that remain to be considered.

Soil evaporation and transpiration will be considered, first, for irrigated lands, and second, for the general grass and alkali area of the valley floor. The quantity of water used in irrigating the 3 011 acres under cultivation in the region is about 72 sec-ft. of continuous flow for 6 months (Table 18), which is equivalent to a depth of 8.6 ft. over the whole area. The depth of transpiration from alfalfa during the irrigating season has already been computed as 3.43 ft., or 40% of the total volume used. There is also a small loss through evaporation from the soil during and immediately after irrigations, say 0.85 ft., or 10% of the total. The total loss by evaporation from the soil and by transpiration from irrigated areas, therefore, is 4.3 ft. in depth, or 18 sec-ft., of continuous flow.

The bases for computing the evaporation and transpiration loss from grass and alkali land are the soil-evaporation equations of Fig. 10 and the ground-water contours of Plate VI. The equations were developed for a fixed ground-water surface, but they cover the periods from October 1st to March 31st and from April 1st to September 30th, which practically coincide with the observed periods of rising and falling ground-water. Hence, to cover the natural conditions of fluctuating ground-water surface, average annual depth to ground-water at a given point may be substituted in the equations instead of fixed ground-water depths. The average annual depth to ground-water, in feet, and the depth of evaporation, as determined from the equations for 1911, are given in Table 15 for the non-irrigated areas enclosed by the 3-ft. contour and between the 3- and 4-ft. and 4- and 8-ft. contours. The volume annually evaporating from the whole area enclosed by these contours is equivalent to a continuous flow for the year of 109 sec-ft.

The water of Blackrock and Hines Springs, and of the small springs along the upper edge of the valley floor, spreads out in many shallow lake basins before reaching Owens River. The loss by evaporation from the surface of these lakes is large. Estimates based on the area of water surface exposed and the evaporation from water in the shallow pan in soil indicate that about 50% of the flow of these springs thus escapes into the atmosphere. As the combined flow is 31 sec-ft., the loss by evaporation from the free water surface is 15 sec-ft. The portion of the remainder which does not flow into Owens River percolates into the soil and escapes by evaporation from the soil and by transpiration.

Two springs derive their waters from percolation and discharge directly into Owens River; these are Upper and Lower Seeley Springs. Their combined average flow is 11 sec-ft. In addition, the Blackrock Springs discharge an average of 7 sec-ft. into the river during November to March, inclusive, which is equivalent to a continuous flow of 3 sec-ft. The total discharge into the river from springs, therefore, is 14 sec-ft.

The grand total ground-water losses, therefore, are 156 annual sec-ft., of which which 127 sec-ft. or 81% is by soil evaporation and transpiration.

Rate of Recharge by Percolation.

From Precipitation.—All portions of the region receive precipitation, but there is wide local variation in the quantities which enter the ground and percolate downward to the surface of saturation. The impervious rock surfaces of the high mountain drainage areas shed

all precipitation which they receive except that lost by evaporation, but accretions to the ground-water from precipitation on the remaining areas of the region are of considerable importance.

Conditions are exceptionally favorable for percolation on the intermediate mountain slopes. As has been stated, the formation is very porous, and practically none of the run-off reaches living streams. All precipitation but that lost by evaporation, therefore, can be considered as percolating downward to the surface of saturation and becoming a permanent addition to the ground-water supply. Snow is practically all melted before May 15th, so that the period of direct exposure to evaporation is not as long as at higher levels, although the rate is greater. Evaporation losses from the moist soil are very small. Before it is melted, the snow blanket protects the soil surface, and by its gradual and uninterrupted melting it fills the capillary spaces to considerable depth, so that gravity water passes downward rapidly. When the snow disappears the rapid drying of the soil surface soon interrupts upward capillary movement, thus preventing further evaporation loss and allowing the percolating water to reach the surface of saturation. In view of these facts, the percolation factor is regarded as being about 0.75 for the more elevated areas receiving approximately 20 in. of precipitation. Less favored areas were assigned smaller factors after a study of their individual characteristics.

The results of computations of the total quantity of percolating water yielded by the intermediate mountain slopes are shown in Table 16. The method was to determine the mean seasonal precipitation at the center of area of each triangular subdivision, multiply this by the area in square miles, and apply a percolation factor. The area of each subdivision and the horizontal and vertical position of its center were obtained from Table 3. Diagrams 7, 8, 10, 11, 13, and 14 on Plate III were used in determining the depth of precipitation. The values differed slightly, as read from the altitude and distance diagrams, and the average was adopted as the most reliable. The total volume of precipitation on the 29.4 sq. miles of intermediate mountain slope is 27 580 acre-ft., of which 19 700 acre-ft. is a permanent addition to the underground water supply of the region. Expressed as a continuous flow, the total percolation from this area is 27 sec-ft.

The outwash slopes yield to the underground supply a much smaller volume of water, which is derived principally from slopes above

the 5 500-ft. contour. Precipitation occurs as snow less often here than on the higher slopes, and usually melts within a few days after falling. The capillary water in the upper layers of the soil thus has opportunity to evaporate after each storm, and it is only when several storms occur in succession that there is enough percolating water to

penetrate the ground beyond possibility of return. The long dry summer and the desert conditions draw all moisture from the ground to considerable depths, and the progress of percolating waters is slow because the capillary spaces must be refilled. Test pits dug in the region of the 4 500-ft. contour, 10 days after a series of storms, showed a penetration of capillary water to a depth of 4 ft. and the entire absence of gravity water. The total precipitation from these storms at this point was about 3.5 in., which, with a 28% available pore space, would represent 1 ft. of completely saturated soil. Considering the evaporation losses, it is not surprising that there was no gravity water within the depth of penetration observed. Observations made at higher elevations after this storm showed gravity water in considerable quantity at a depth of 12 ft. Percolation factors varying from zero to 0.60 were assigned to the several zones of the outwash slope as a result of these field observations.

The results of computations for the total quantity of percolating water yielded by the outwash slopes are shown in Table 17. The whole area of 165 sq. miles was divided into zones lying between contours at 500-ft. intervals from about 4 000 to 6 500 ft., and the zones in turn were divided into groups corresponding with the precipitation gauges. The method of computation was to average the precipitations for adjacent contours obtained from Diagrams 7, 8, 10, 11, 13, and 14 of Plate III. These averages represented the average precipitation for each zone in each group and, when multiplied by the area and the percolation factor, gave the quantity of percolating water which reached the permanent ground-water level. The total annual precipitation on the outwash slopes is 62 000 acre-ft., of which 16%, or 9 800 acre-ft., is effective percolating water. Expressed as a continuous flow, the volume of percolating water amounts to 13.4 sec-ft.

Throughout the valley floor the surface of saturation is so close to the ground surface that capillary connection is maintained during most of the year, and percolation from precipitation is rapid. The depth of penetration is usually slight, however, because precipitation in single storms is small. Several storms in succession or a warm rain on snow will result in a rise of ground-water, but the total average ground-water supply from this source does not exceed 4 sec-ft.

Direct percolation from precipitation, therefore, furnishes a grand total of 44 annual sec-ft. to the underground supply of the basin.

From Stream Channels.—The most important source of underground water in a desert region is percolation from stream channels. This process is continuous from perennial streams, although it varies with the discharge of the streams and the temperature, as previously indicated. Beneath each stream channel as it crosses the outwash slope is a "ridge" of ground-water rising from the general plane of satura-

tion. The inclination of the slopes of this ridge and the breadth of its base vary periodically with the stage of the creek and the time of year. There is complete saturation within its slopes and a movement of gravity water toward the general ground-water surface. A considerable quantity of water also percolates from intermittent streams.

Percolation from stream channels in the Independence Basin is confined to the creeks draining mountain canyons. There are 17 of of these streams, 11 of which are perennial throughout their channels, 5 are perennial over the upper portion of their channels only, and 1 (Dry Canyon) is entirely an underground stream. The surface flow of the two most northerly of these streams, Tinemaha and Red Mountain Creeks, discharges northward across the Poverty Hills into the Bishop-Big Pine region, but the percolation from their channels is tributary to the Independence Basin. The channels of streams entirely within the basin are continuous from their canyons to the U. S. Geological Survey gauging stations, below which they divide, irrigation ditches carrying all the flow except during the high-water period of wet years, when the excess passes down the natural channels. The problem is thus divided into the determination of percolation above and below the Government gauging stations. The first subject has already been discussed at length and need not be considered here in detail. An inspection of Tables 4 and 5 shows that for the creeks from Taboose to Hogback, inclusive, the total 21-year average discharge at the mouths of the canyons is 130 sec-ft. and at the Government gauging stations 84 sec-ft. If the flow of 2 sec-ft. from Spring No. 2 on Division Creek is included with the canyon discharge, the percolation loss above the Government gauging stations is 48 annual sec-ft. To this should be added 6 sec-ft., as indicated by the diagrams, for Tinemaha and Red Mountain Creeks, making a total of 54 sec-ft.

The quantity lost below these stations is not so easily determined, on account of the numerous channels and irregular flow. Estimates were made on each creek, based on the length of main channel and distributing ditches outside of irrigated areas. The loss per mile was assumed to be the average annual loss per mile for the upper channel of the creek, and the total percolation loss from stream channels below the Government stations was estimated at 25 sec-ft. of continuous flow. This estimate does not include percolation from waste irrigation water or surplus creek water which has passed east of the ranches.

The grand total addition to the underground supply derived by percolation from stream channels, therefore, is 79 annual sec-ft.

From Irrigation.—Irrigation has been practised throughout this region, in connection with farming, for at least 30 years, and is a permanent factor in the underground water problem. The total area under systematic irrigation is approximately 3 000 acres, divided into a number of isolated ranch groups which depend on the mountain creeks for their supply. Oak Creek, the largest of these streams, supplies about 45% of the whole area. The remaining area is divided among eight creeks and the Stevens ditch, which during the period of observation has been largely supplied by the surplus flow of the creeks. The acreage irrigated from each source is given in Table 18. About 50% of this land was originally desert, lying along the lower margin of the outwash slope, and is very porous. The remainder lies in the valley floor, where permanent ground-water is within reach of plant roots and where clay soils predominate. The location of the several areas is shown on Plate VI. Alfalfa and grain are irrigated by

flooding, and corn by the furrow method. Three crops of alfalfa are raised each year, and the irrigating season extends from about April 15th to October 15th, although some farmers irrigate 9 months in the year. Grain is irrigated early in the season, and corn late, so that the water is continually used. In most places the use of water is lavish, and no attempt is made to economize it or even to apply the quantity best suited to the crop and soil conditions.

A basis for determining the percolation from irrigation is a knowledge of the duty of water, or the quantity of water used in maturing a given area of crop. This was obtained in 1909 by carefully measuring the quantity of water used daily during the irrigating season on five typical ranches which derived their supply from Oak Creek. On ranches where there was a continual waste from irrigation the surplus water was also measured. Areas in crop were obtained from a careful stadia survey of each ranch.

With conditions on these typical ranches in mind, an examination was made of all other ranches in the region, and values were estimated for the duty of water on each. The number of acres irrigated and in crop was also determined approximately by reference to subdivisions of the public survey. From these data the volume of water used for irrigation was determined, as shown in Table 18. The total volume used during the 6 months, April 15th to October 15th, is about 26 000 acre-ft., equivalent to a continuous flow of 72 sec-ft. during the period. When spread out over 3 010 acres, this represents an average depth of 8.6 ft. This result probably represents an average practice throughout the Owens Valley, for the duty of water measured by the Reclamation Service during the season of 1904 on two typical ranches near Bishop was 7.11 and 9.17 acre-ft. per acre.

The distribution of this water, as regards evaporation, transpiration, and percolation beyond the reach of plant roots, is the next step in computing the ground-water supply from this source. Direct evaporation is relatively small, for the water when spread out over the fields is shaded by the crop and sinks rapidly into the ground. Probably 10% would cover this loss. The transpiration loss from alfalfa during the irrigation season has already been computed as 3.43 ft. depth of equivalent water, or 40% of the average volume of water applied to crops. The transpiration loss from corn and small grains is probably less in this locality, but the direct evaporation loss is greater. There-

fore 50%, or 4.3 ft. depth, represents the quantity of water applied in irrigation in this region which is absorbed by the atmosphere. The other 50% is a permanent addition to the ground-water supply, and is equivalent to a continuous flow of 18 sec-ft. throughout the year.

From Flood Water.—The quantity of percolation from surplus creek water, which spreads out over the valley floor to a greater or less extent, is difficult to determine. Of the 84 sec-ft. average flow at Government gauging stations, 61 sec-ft. are disposed of in channel percolation and irrigation. Possibly 5 sec-ft. of the remainder reach Owens River. This leaves 18 sec-ft. to be divided between evaporation and percolation in the flats between the ranches and the river. The area flooded averages about 5 sq. miles during June and July. The loss by evaporation during this period from a shallow pan in soil was about 24.5 in., and, as the conditions are similar, this represents approximately the loss from shallow flood water. The volume expressed as a continuous flow for two months is 55 sec-ft., or, for a year, 9 sec-ft. The other 9 sec-ft. can be assumed to represent the percolation from this flood water. It is not a permanent addition to the ground-water supply, however, for the surface of saturation is only a few feet below the ground surface in this area, and evaporation from damp soil and transpiration from natural vegetation soon reduce the ground-water surface to its normal position.

Summary of Percolation.—The four sources of ground-water are percolation from direct precipitation, from stream flow, from irrigation, and from flood water in the valley floor.

The first of these yields about 44 annual sec-ft., of which 61% is from the intermediate mountain slopes, 30% from the outwash slopes, and 9% from the valley floor. Percolation from streams yields about 79 annual sec-ft., of which 68% is above Government gauging stations and 32% below. Irrigation yields 18 annual sec-ft. and flood waters in the valley floor 9 annual sec-ft.

The grand total ground-water, therefore, is 150 annual sec-ft., of which probably 75% reaches the deeper strata of the valley fill. The rate of recharge of the basin, as thus determined, differs by less than 4% from the ground-water loss previously computed. The reliability of the data is thus confirmed as well as the correctness of the assumptions.

Safe Yield.

Thus far, this paper has presented conditions as they are found to exist in a natural state. The problems which the engineer has to solve are those connected with the artificial extraction of water from underground reservoirs. First among these is the determination of the safe annual yield or the limit to the quantity of water which can be withdrawn regularly and permanently without dangerous depletion of the storage reserve. A second problem which naturally accompanies the first is the devising of methods for increasing artificially the safe annual yield of reservoirs which are apparently already developed to the limit. The writer will outline his ideas, in the hope that they will suggest a constructive line of discussion which will lead to a better understanding of these subjects.

It is obvious that water permanently extracted from an underground reservoir, by wells or other means, reduces by an equal quantity the volume of water passing from the basin by way of natural channels. This is illustrated by the commonly recognized fact of the drying up of springs and cienagas as the result of heavy pumping. The theoretical limit for safe draft, exclusive of return water, therefore, is the average rate of recharge for a basin. The practical limit, however, depends on the relation of draft to storage capacity, within economic pumping limits. Where the storage capacity is very large as compared with annual draft, the theoretical and practical limits should nearly agree, as the storage reserve can be drawn on in periods of protracted drought. For basins with comparatively small storage capacity, the practical limit will be less than the theoretical. Draft computations may be made with the mass-diagram as ordinarily used in surface storage problems. Storage capacity is determined from the area of water-bearing material, limiting depth for economic pumping, and percentage of voids capable of depletion. The supply is the quantity of water annually absorbed by the porous material of the basin. This may be determined each year by methods similar to those used in the Owens Valley studies.

The draft thus obtained, however, is not the safe yield of the basin, for there are always certain residual losses which cannot be entirely prevented, such for instance as soil evaporation from cienaga lands. These residual losses must be ascertained and deducted from the gross draft. The quantity thus obtained may be persistently with-

drawn from the basin without causing general depression of the water plane to the point where pumping operations must cease for economic reasons.

The determination of residual losses presents difficult problems. Some of the conditions which are responsible for these losses are the following:

1.—The elevation of the impervious rim at the outlet being less than the elevation of the water plane in the lowest depression of the basin, thus allowing ground-water to escape as underflow. The quantity of water thus dissipated depends on the transmission capacity and area of the porous material overlying the rim and the available head. In most cases the volume of water thus lost is relatively very small.

2.—The outlet of springs being at a considerably lower elevation than the general water plane of the basin in the outlet region. Such a condition may exist where an arroya has cut a channel through the impervious rim at a point where the surface falls away rapidly down stream. Such losses are also relatively small.

3.—The occurence of water under Artesian pressure in underlying strata of porous material confined between more impervious layers of fine sand or clay. This is the least recognized, but yet the most important, cause of residual ground-water loss. The effect of Artesian pressure is to force moisture through pores or fractures in the impervious capping and thus maintain a permanent ground-water plane near the surface. The water continually supplied from below is disposed of either by evaporation from the soil surface and vegetation or by escaping at the surface in springs or seepages. These losses persist as long as the Artesian pressure is sufficient to force the water through the overlying strata. The volume of these losses during any period of one or more years bears a functional relation to the average Artesian pressure during the same period. The writer states these conclusions as the result of a careful study of records and conditions in a number of differently situated Artesian basins.

These conclusions are well illustrated by the following facts of common knowledge. First, consider the result of abnormally large precipitation for a period of one or more seasons. The ground-water accretions exceed the losses from the basin, the excess water accumulates in the voids of the porous gravels surrounding the confined strata,

and the free ground-water surface rises throughout the basin. Within the area of confined gravels hydrostatic or Artesian pressure increases. A greater quantity of water is forced through the overlying strata, not only over the area already moist, but from a circumscribing zone within which the pressure was previously insufficient to maintain a shallow ground-water surface. The observed result, therefore, is increased spring and seepage flow and an enlarged area of moist cienaga land from which evaporation occurs. Second, assume a series of dry years. Ground-water storage is depleted, the free ground-water plane falls, Artesian pressure decreases, and less water is forced through the overlying strata. The observed result is decreased spring and seepage flow and shrunken evaporating area. The latter occurs, because, for the new conditions, the rate of evaporation from the outer zone of moist soil exceeds the rate of supply from below. The accumulation of water in the soil is drawn on, lowering the water level to the limit of capillary action. A similar result occurs where relief is afforded to Artesian pressure by the drilling of many deep wells drawing from Artesian strata. In some of the Southern California Artesian basins, which formerly possessed cienaga lands, relief of Artesian pressure by wells and heavy pumping has dried up such lands.

The importance of residual losses, due to Artesian pressure, is forcibly shown by the Owens Valley studies, where it was found that in a natural state 81% of the total yield of the Independence Basin was lost by evaporation from soil and vegetation. Similar conditions, in a slightly less degree, existed in many of the Southern California basins before ground-water development was undertaken. The increased pumping of the last 10 or 15 years has eliminated evaporation losses almost entirely in some of the smaller basins. In the larger basins, such as the San Bernardino Valley and Coastal Plain, the reduction has not been as great, having ranged from 30 to 50% of original evaporation losses in the various basins. In these basins evaporation losses formerly represented from 50 to 75% of the total ground-water supply. Hence, the residual evaporation losses to-day represent from 15 to 35% of the total ground-water supply for the large Southern California basins, and can be said to average 25 per cent.

The quantitative determination of the residual losses from an underground reservoir can only be made after a detailed study of the local

conditions. The factors to be considered are the topography and geology of the basin and its porous filling, the distribution and type of sources of percolating water, the rate of evaporation and transpiration, the depth of capillary action and the character of the soil within the evaporating area, the necessity for irrigation and the value of overlying lands for agricultural crops, the present or probable ultimate method of development of water, and the present or probable future use. The general condition favorable for small residual losses is the possibility of eliminating the evaporating area by lowering the water plane below the reach of capillary action. This may be done by the relief of Artesian pressure, by shallow pumping within the evaporating area, or by drainage. The first of these methods would result in reduced pressures in existing wells in the Artesian area and possibly lowered water levels in the back-water zone, especially if the ground surface has a steep slope. Shallow pumping and drainage, on the other hand, may be physically impractical or prohibitive in cost. Their success depends largely on the existence of shallow water-bearing strata from which water can be readily drawn.

There are three cases which arise in the determination of residual losses: first, a basin already fully developed or suffering from overdraft; second, a basin where the supply is partly developed; third, a basin entirely undeveloped. The first case can be recognized by inspection of the present or former evaporating area in connection with local confirmatory evidence and past records of water levels, yield of wells, etc. The residual losses may be ascertained from observations and measurements of existing conditions. The second and third cases require assumptions as to the method or combination of methods by which residual losses will be reduced to a minimum. These assumptions should be made after a careful study of local physical conditions and the probable future use of the water. The next step is the determination of existing evaporation losses, by contouring the ground surface and water plane, and ascertaining the soil evaporation losses for various depths to ground-water. The final step, namely, the determination of the percentage by which existing losses will be reduced by future development, is as yet largely a matter of judgment. Having arrived at some definite value, however, the residual losses due to evaporation can be computed, and, when combined with the losses from underflow or deep springs, the total quantitative result is obtained.

The thorough investigation of residual losses is essential in any determination of safe yield, and for this reason the writer has discussed the subject in detail.

Passing now from the determination of safe yield as limited by existing conditions to a discussion of methods for increasing safe yield artificially. Obviously, to accomplish the latter, either the rate of recharge of the basin must be increased or the percentage of unused water escaping from the basin must be decreased. Practical methods which suggest themselves are:

(1) Reduction of residual losses to the lowest possible quantity;
(2) Elimination of needless waste of underground water; and
(3) Increased absorption of surface flood waters.

The subject of residual losses has already been discussed at length. The writer wishes to emphasize the fact, however, that a basin has not been fully developed as long as the evaporating area persists in years of drought. The evaporating area is fully as important a criterion of the relation of withdrawals to supply as the water plane. A falling water plane does not of itself indicate overdraft. It is only when a rapid shrinkage and disappearance of the evaporating area accompanies a falling water plane that dangerous overdraft is indicated. Hence, in a closed Artesian basin from which the evaporation area has not disappeared, a greater yield may be obtained, provided an intelligent plan of development is followed.

A very common source of needless waste is from Artesian wells which are allowed to flow when the water is not in use. The wastefulness of this practice is so evident that it need not be discussed in this paper. Its continuance is made possible by lack of recognition of the ultimate effect of the practice among the owners of such wells. The writer feels that it is every engineer's duty and privilege to assist in guiding aright public opinion in matters of common interest, and suggests the subject of conservation of Artesian water as being pertinent in many communities.

The practicability of increasing the ground-water supply by bringing about greater absorption of flood water has been demonstrated in a number of California basins. The most extensive work of this kind is probably that done on the alluvial cone of Santa Ana River in the San Bernardino Valley. The method there used is to divert the flood

water of Santa Ana River in contour ditches from which it is distributed into smaller ditches which in turn subdivide, until finally the water spreads out over the porous alluvial gravels in a thin sheet and is absorbed. During the past few years the volume of water thus stored has averaged 12 000 acre-ft. annually, costing about 15 cents per acre-ft., including interest on the cost of permanent works. The work is capable of further expansion. The ultimate limit will be the ability to handle the violent floods which are of frequent occurrence. The problem is not that alone of controlling the water, but of disposing of silt. The water is normally clear and is free from silt soon after the flood crest passes. Flood water, however, carries great quantities of silt, which deposits as soon as the velocity is checked. This forms an impervious layer of slime which seals the gravels and must be broken up and eventually removed in order to use the same spreading ground continuously.

The conditions on most California streams tributary to closed basins correspond with the Santa Ana. The writer is of the opinion that complete absorption of even ordinary floods on these streams cannot be brought about without temporary surface storage. This must be accomplished either by utilizing storage sites in the stream channel or by construction of contour levees on the alluvial cone. The purpose of such reservoirs would be to act both as settling basins and as temporary storage sites. From these reservoirs the clear water would be released and brought into contact with the absorbent gravels by any method which proved most efficient under the local conditions.

In conclusion it may be said, first, that the rate of recharge of underground reservoirs of the closed-basin type is a definite quantity capable of measurement with a fair degree of accuracy; second, that safe yield is a quantity less than the rate of recharge, its quantity depending on the available storage reserve of the basin and residual ground-water losses; third, that under certain circumstances it is possible to increase the safe yield of a fully developed basin.

CINDER CONCRETE FLOORS.

By Guy B. Waite, M. Am. Soc. C. E.

To be Presented May 6th, 1914.

Summary.

In the following paper the manner of using reinforced cinder concrete floor slabs by various cities in the eastern part of the United States is described. Especial attention is called to the arbitrary manner of using this material, and the insistence of continuing this arbitrary use, by New York City, as indicated by the latest building codes.

Attention is called to the unit stresses adopted by various cities and to recent data tending to establish unit working stresses from actual tests. The qualifications of this material for the purposes described are discussed, and a comparison with stone concrete is made.

The manner of arbitrary testing is described, and the difference between the conditions of such tests and the actual loadings found in buildings is pointed out.

Analysis is made of the arbitrarily approved reinforced cinder concrete floor slabs, showing the stresses which would be imposed on the materials by the maximum approved loads.

Cinder concrete is described and tabulations are made for the location of the neutral axis and for the carrying capacities, assuming various unit stresses. The influence of the stresses due to an excess of steel or to an excess of concrete is discussed.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

Analyses of stresses allowed by such tests indicate that in some cases approvals have been given for dangerous construction; it is pointed out that arbitrary tests can be made which indicate carrying capacities not possible under the conditions actually found in buildings; and it is shown by formulations and tabulations that reinforced cinder concrete may be easily and uniformly designed by adopting working unit stresses, and that several cities have adopted such stresses for this material.

The writer believes that in this paper he has amply demonstrated that the only manner in which this material can ever be uniformly used under various conditions is for each locality to adopt unit stresses suited to its own conditions.

Where cinders of good quality can be obtained, cinder concrete, reinforced with steel, for fire-proof floor construction, is used very extensively in the eastern part of the United States. It is estimated that more than 50% of the large fire-proof constructions of Philadelphia, Pa., have reinforced cinder concrete floor slabs, and New York City has probably a larger proportion.

Floor slabs of stone and gravel concrete, reinforced with steel, of the same general form as cinder concrete, have been systematized by engineers so that they are being used on a rational basis; but cinder concrete has been allowed to straggle along, without much attention from engineers in general, and is being used in a varied manner. Most large cities, such as Philadelphia, Pa., Boston, Mass., and Chicago, Ill., require cinder concrete for floor slabs to be designed, in thickness and in quantity of reinforcement, with certain values of unit stresses as a limit.

In New York City, and in most small cities of the eastern part of the United States, unit stresses are not considered in the use of such concrete. In these places, the use is either entirely arbitrary or a separate test is required for each condition.

In New York City, since the beginning of the use of cinder concrete floors, in 1896, there have been some 200 approvals for reinforced floor slabs of this material, based on load tests. These approvals were for varying spans, thicknesses of concrete, and quantities of reinforcement. The tests have generally been conducted with a uniformly

distributed load—of pig iron, bags of cement, or sand—imposed on the slab.

As will be shown in detail, the results of former tests, which include all principal constructions in use, are extremely variable. The writer has been informed that since 1911 concentrated load tests are required for all new approvals, by the Borough of Manhattan, New York City. The result is that now there are approvals of concrete floor slabs in which the effective depth is 3 in. (4 in. total thickness) and the reinforcement is less than ½ lb. per sq. ft. on an 8-ft. span, and with a live floor load of 250 lb. per sq. ft. In these slabs the concrete is in the proportion of 1:2:5.

One of the dealers in reinforcing materials for cinder concrete publishes a statement of what he calls its "authorized use" by the Boroughs of Greater New York City. This is a 1:2:4 mixture, with a 5-in. effective depth up to 12-ft. spans for live loads of 60 lb. per sq. ft.—or a total load of about 120 lb.

Each contractor in New York City is held strictly to the details of construction for his approvals. For instance, if the approval allows a live load of 250 lb. per sq. ft. up to 6-ft. spans, and it is desired to use the construction for a live load of only 60 lb. per sq. ft., on 6 ft. 6-in. spans, this construction will not be allowed for this excess of 6 in. in span, though stressed less than with the approved loads.

Moreover, stone and gravel reinforced concrete floor slabs are required to be designed according to the following values: Extreme fiber stress in concrete, 650 lb. per sq. in.; maximum tension in mild steel, 16 000 lb. per sq. in.; ratio of moduli, 15. According to these values, stone concrete slabs in some instances would be designed with a greater thickness and have greater reinforcement than the approvals for cinder concrete.

The writer believes that the excuse, that cinder concrete is so extremely variable as not to permit of the assignment of unit stresses, is not well founded. The fact that cinder concrete is being used extensively in engineering construction is sufficient reason for assigning, for safety, some unit stresses, in order to insure uniformity. The present manner of making arbitrary approvals has led to confusion, various forms of reinforcement obtaining approvals in which the spans, thicknesses of concrete, quantities of reinforcement, and floor loads vary beyond description.

The proposed building codes of 1912 and 1913 have persistently continued the present manner of using cinder concrete (with slight modifications) for floor constructions.* In these codes, the manner of designing and constructing cinder concrete floor slabs is arbitrarily specified. In the proposed code of 1913, the allowed carrying capacity of the slab with 3 in. effective depth on 8-ft. spans is increased (over the 1912 code) to a live load of 250 lb. per sq. ft.

It is on account of these conditions in the uses of cinder concrete that the writer has been prompted to bring this matter before the Society, with the hope of interesting the Engineering Profession in a subject which should be of vital concern to many.

Cinders.—Cinders for concrete floor construction are understood to mean either hard or soft coal ashes coming from boiler plants. Coal ashes from a stove or a small house boiler are generally too finely burned to be of use in this kind of concrete. Cinders from either hard or soft coal, and having sharp particles greatly in excess of the smooth ashes, make a concrete of considerable strength and of good fire-resisting qualities.

Cinders vary in size from the consistency of coarse building sand to clinkers several inches in diameter. Some hard-coal cinders run so perfectly in grade that good concrete is made without the addition of sand; more often, however, sand must be added. The quantity of sand required to fill the voids is variable, but the usual specification is 2 parts of sand to 5 parts of cinders.

After a long experience in the use of cinder concrete, the writer believes that there should be no danger in assigning working stresses to the material, these stresses being taken from tests on known mixtures in which cinders of the lowest grade permitted are used. If the material is too poor to have such working stresses assigned, it seems evident that cinder concrete is not a safe material for such an important part of the structure as the floor slab.

Cinder Concrete as Fire-Proofing.—Since 1896 some 82 different floor constructions have been tested in the United States by fire and water. Nearly all these tests were made under the auspices of the Bureau of Buildings of New York City, on full-sized floor slabs. About 40 of the tests were on reinforced cinder concrete floor slabs, some 23

* Sec. 113, proposed code of 1912; and Sec. 104, proposed code of 1913.

on stone or gravel concrete floor slabs, 10 on some form of hollow tile, and the others on special floor constructions.

The test structures were about 14 ft. square and 9 ft. high, with a fire grate at the bottom and the floor slabs to be tested forming the ceiling. The average temperature on the tested floor slabs was 1 700° Fahr. maintained for 4 hours. Following this there was a water test of 60 lb. pressure through a 1¼-in. nozzle applied for 10 min. to the under side of the slabs. During the fire test a load of 150 lb. per sq. ft. remained on the entire surface of the slabs. After the fire test the slabs were subjected to a total load of 600 lb. per. sq. ft. Fig. 1 is a view inside one of these test structures after a fire test.

In these tests, the cinder concrete floor constructions withstood the fire and water better than any other material. In the writer's opinion, the reason for this is not due to cinder concrete being more fire-proof than the others, but simply to the fact that it is not ruptured and destroyed by the expansions and contractions caused by fire and water.

Hollow tile, as a material, may be more fire-proof than cinder concrete, but the stresses due to the expansion of the exposed surface, destroy it.

The test structure, an inside view of which is shown, was built entirely of cinder concrete, mixed 1 to 4 without sand, and withstood four different fires before being torn down to make room for improvements. Only the surface, for a depth of less than 1 in., was affected; this was dehydrated, but the burned cinder concrete was still intact, and protected the remainder of the material. In this concrete there was at least 5% of unburned pea coal which was unaffected by the fire.

Arbitrary Testing of Cinder Concrete.—In New York City after each type of cinder concrete construction had qualified for fire-proofing, the variations in spans, carrying capacity, etc., were determined by each manufacturer by constructing the slabs he proposed to use and testing them with uniformly distributed loads under the supervision of the Bureau of Buildings.

This was the method used for the approvals of the constructions shown, with the exception of Fig. 5, which was constructed for fire test. These constructions were taken from the files of the Bureau of Buildings from among some 200 similar approvals.

For comparison with the approved cinder concrete floor slabs shown by Figs. 3 to 7, the writer gives the relative thicknesses and the quantity of reinforcement for slabs under similar conditions according to the unit stresses used by Philadelphia, and also the thicknesses and quantity of reinforcement required by New York City for 1:2:4 stone concrete.

It is to be noted, in comparing the stone or gravel concrete construction (Figs. 11 to 13) with the cinder concrete, that the former is made unquestionably continuous, and the latter, in most cases, is cut into and is simply supported by the steel beams (Figs. 3 to 10, and 14 and 15).

The approvals for the longest spans with the highest carrying capacity were based on tests with slabs which were continuous over supports (Figs. 3 to 7). In practice, it is seldom that cinder concrete floor slabs between steel beams can be made continuous throughout a floor.

In Figs. 14 and 15, which are assumptions for illustration, it will be noticed that the reinforcement is simply laid over the top flanges of the supporting steel beams. In practice, there is no way of taking up the slack in the reinforcement coming over the tops of the beams, and the consequences are that under such conditions there can be no continuous action—such as engineers understand—in the combined steel and concrete structure. Unless considerable slack is allowed on the sides of each supporting beam, the tamping of the concrete works the reinforcement to the top of the slab.

In buildings where a wooden floor is used, the sleepers are generally laid directly on the steel beams, and consequently the concrete is kept below the top flanges of the beams. Here, therefore, the concrete is not continuous in any part of the floor; but in the interior spaces on all floors, whether continuous or not, the channels on the outside spans, and against openings in floors, cannot have either concrete or reinforcement continuous over them (Figs. 14 and 15).

To any one acquainted with the actual construction of cinder concrete floors, it must be apparent that some parts of each floor will not admit of being constructed with the same care that might be attained in a test construction; therefore it does not follow that because a slab was continuous in the test, it is so in actual practice.

Again, these tested slabs were held by adjacent slabs on each side of the supports, thus enabling each side to take thrust. Now, in practice, outside slabs next to walls, elevator shafts, stairways, show windows, etc., are only resisted for thrust by tie-rods and by concrete slabs on one side.

If the writer is correct in his statement that outside slabs, etc., are not under the same conditions as the tested ones, where the reinforcement and the concrete is carefully made continuous, then this form of so-called continuous construction is being used in an unapproved and unsafe manner.

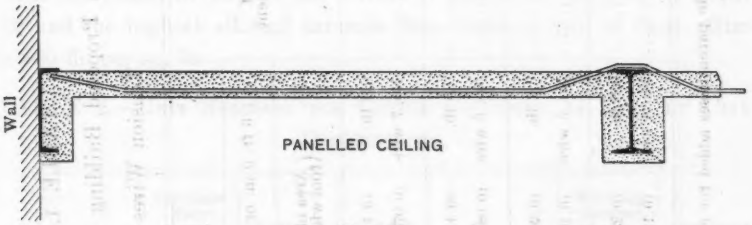

FIG. 14.

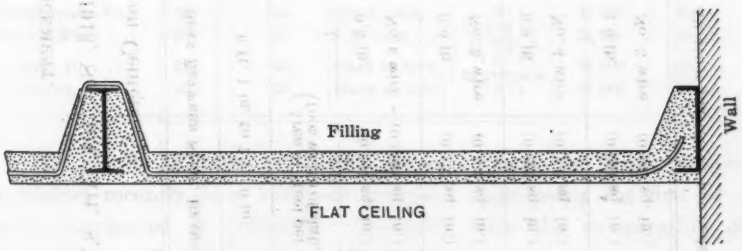

FIG. 15.

The tests on which the approvals were based had the kind of loadings heretofore mentioned. Fig. 2 shows a test loading similar to those described.

With the conditions of continuous construction under which these slabs were tested, with possible arching of loading, and with supports braced against side flexure, the stress that came on the steel and concrete at the middle of the slab can only be guessed. Still, according to the latest proposed building code (that of 1913) tests and

201 to 250 lb.	Bars	0.8 lb.	(0.236 sq. in.)	1.0 lb.	(0.294 sq. in.)	1.2 lb.	(0.353 sq. in.)
	Wire mesh	No. 4 wire	(0.120 sq. in.)	No. 3 wire	(0.140 sq. in.)	No. 2 wire	(0.162 sq. in.)

Matter in parentheses added for comparison. All other matter as per code.

approvals of that kind were to have preference over unit stresses. The following is quoted from Sec. 104, Art. 8, of this proposed code:

"The concrete is made 1, 2, 5; slab thickness, 4 in., with reinforcement 1 in. from bottom.

"Reinforcement must be as per tabulations."

It will be noticed from Table 1 that when the reinforcement is of wire mesh the area required is only about one-half as great as for any other form of reinforcement—even with the same kind of wire but without the mesh.

Use of Cinder Concrete by Cities Other than New York.—The cities mentioned in Table 2 use a ratio of moduli of elasticity of about 30, and the highest allowed extreme fiber stress in any of these cities is 300 lb. per sq. in.

TABLE 2.—UNIT STRESSES FOR CINDER CONCRETE, AS USED BY CITY DEPARTMENTS.

City.	Extreme fiber stress, in pounds per square inch.	Ratio of moduli of elasticity.	Kind of cinders used.	Mixture.	Working stresses in steel, in pounds per square inch.	Preferred reinforcement.
Philadelphia, Pa.	250	30	Hard coal...	1 : 2 : 4	16 000	None.
Boston, Mass....	300	25	Soft coal....	1 : 2 : 4 to 1 : 2½ : 5	16 000	None.
Chicago, Ill.....	245	30	Hard or soft.	1 to 8 aggregate.	18 000	None.
Baltimore, Md...	300	30	Hard or soft.	1 : 2 : 4.	15 000	None.

The results of tests on cinder concrete quoted in Table 3 were published recently in a technical journal,* these being the first of a series conducted at Columbia University with the co-operation of the Bureau of Buildings of New York City.

Though the limited tests in Table 3 would seem to show that a ratio of moduli of less than 30 could be used, the writer has been informed that specimens "C" were from extra good concrete, and that "A" and "B" are nearer the average material. In this case the ratios used by Philadelphia, Chicago, and Baltimore seem to be about right. As will be seen later, a less ratio of moduli will give a less carrying capacity, other things remaining the same.

**Engineering News*, October 9th, 1913.

In the tests at Columbia University, just referred to, it is the feeling, at the present stage of these tests, that an extreme fiber stress of from 200 to 250 lb. per sq. in. on cinder concrete is all that can be used conservatively.

Only the tests up to 6 months old have been made; the final tests may alter this assumption, but, for discussion, these values are sufficiently correct.

TABLE 3.

"WEIGHT AND COMPRESSIVE STRENGTH OF CINDER CONCRETE AS USED IN FIREPROOF FLOORS, NEW YORK CITY.

(The table covers 120 samples. Each figure given is the average of ten samples.)

Zone.	A.	B.	B2.	C.
Mix	1:2:5	1:1:5	1:2:5	1:2:5
Weight, lb. per cu. ft.	107	100	107	109
One-month Test:				
Crushing Strength, lb. per sq. in.	407	507	818	980
Mod. of Elast., lb. per sq. in.	924 600	857 400	1 280 000	1 492 000
Two-month Test:				
Crushing Strength, lb. per sq. in.	701	662	1 254	1 035
Mod. of Elast., lb. per sq. in.	1 134 000	1 080 000	1 740 000	1 428 250
Six-month test:				
Crushing Strength, lb. per sq. in.	933	754	1 744	1 478
Mod. of Elast., lb. per sq. in.	971 000	1 050 000	1 848 000	1 276 000

NOTE.—B was hand-mixed; A, B2, and C were machine-mixed. The modulus of elasticity was determined at a point of the elastic curve corresponding to one-fourth the ultimate strength."

Designing Reinforced Concrete Floor Slabs.—Solid slabs of cinder concrete are not weak in shear, so that the discussion of vertical and diagonal shear will not be necessary. In the writer's observation of many breaking tests on cinder concrete floor slabs, there has never been a failure near the supports; almost uniformly, the breaking has taken place near the center of the slab. Usually, the top of the central portion has spalled off (cup fashion), apparently due to horizontal shear and compression, after which the slab suddenly collapsed.

Adhesion.—The adhesion of concrete to various kinds of reinforcement is shown by Table 4, the results of a series of tests on 1:2:4 cinder concrete, made in 1904 by Messrs. H. B. Gaylord and H. A. Pratt, at Stevens Institute of Technology. The cement was Lehigh Portland, and the cinders were as found coming from a boiler plant. The concrete blocks were 6 by 6 in., and the steel was embedded in the center.

It may be noted from Table 4 that the plain bars held in adhesion quite as well as the deformed bars; the average adhesion of surface embedded being about 200 lb. per sq. in. This same fact, as to the relative adhesion of plain and deformed steel in stone concrete, has already been shown in numerous tests. Therefore, it will be considered that the form of the reinforcement is immaterial so long as it has sufficient surface embedded.

Bending.—Proceeding on the ordinary assumptions of the common theory of flexure, Fig. 16 is a stress diagram, at the right of which

TABLE 4.—RESULTS OF ADHESION TESTS ON 1:2:4 CINDER CONCRETE.

is shown the strain diagram used in determining the location of the neutral axis. Fig. 17 is for illustration, and Fig. 18 is a heavy-load stress diagram for purposes of discussion.

Let E_c = the modulus of elasticity of cinder concrete;
" E_s = " " " " " mild steel;
" f_c = " extreme fiber stress on cinder concrete (working);
" f_s = " unit allowed stresses per square inch on mild steel;
" a = " area of reinforcing steel, in square inches, or in pounds per square foot;
" y_1 = " distance from top of slab to neutral axis, or
" y_2 = " " " neutral axis to center of gravity of steel;
" d = " distance from center of gravity of steel to top of slab;
" T = " total thickness of the slab; here taken as $d + 1$.

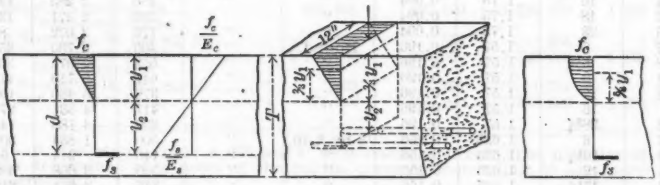

FIG. 16. FIG. 17. FIG. 18.

Referring to the diagram at the right of Fig. 16, it is evident that the maximum strain on the extreme fibers is $\frac{f_c}{E_c}$ and that the strain on the steel is $\frac{f_s}{E_s}$. Both these strains being the bases of two similar triangles, they are proportional to their altitudes, or $\frac{f_c}{E_c} : \frac{f_s}{E_s} = y_1 : y_2$; whence, $y_2 = y_1 \frac{f_s}{f_c} \times \frac{E_c}{E_s}$. If, $\frac{f_s}{f_c} = n$, and $\frac{E_c}{E_s} = m$, then $y_2 = n\,m\,y_1$; but, $d = y_2 + y_1$; hence,

$$y_1 = \frac{d}{n\,m + 1} \qquad (1)$$

Tabulation of Values for y_1.—As there may be differences of opinion as to the proper ratio of the moduli of cinder concrete and steel, the writer has prepared Table 5, giving values for y_1 (the dis-

tance from the top of the slab to the neutral axis) for different moduli, and for different ratios of unit stresses of extreme fiber on the concrete, and tension in the steel.

TABLE 5.—DISTANCE FROM EXTREME FIBER OF CONCRETE TO NEUTRAL AXIS, IN TERMS OF d.

$\frac{E_s}{E_c}$ where $E_s = 30\,000\,000$ and E_c ranges from 800 000 to 2 500 000	y_1 when $\frac{f_s}{f_c} = 80$ i. e., $\frac{16\,000}{200}$ or $\frac{20\,000}{250}$	y_1 when $\frac{f_s}{f_c} = 64$ i. e., $\frac{16\,000}{250}$ or $\frac{20\,000}{312.5}$	y_1 when $\frac{f_s}{f_c} = 53.3$ i. e., $\frac{16\,000}{300}$ or $\frac{20\,000}{375}$	y_1 when $\frac{f_s}{f_c} = 49.3$ i. e., $\frac{16\,000}{325}$ or $\frac{20\,000}{406}$	y_1 when $\frac{f_s}{f_c} = 32$ i. e., $\frac{16\,000}{500}$ or $\frac{20\,000}{625}$	y_1 when $\frac{f_s}{f_c} = 24.6$ i. e., $\frac{16\,000}{650}$ or $\frac{20\,000}{810}$

14.3	0.15d	0.18d	0.21d	0.23d	0.31d	0.37d
13.6	0.15d	0.18d	0.20d	0.22d	0.30d	0.36d
13.0	0.14d	0.17d	0.20d	0.21d	0.29d	0.35d
12.5	0.14d	0.16d	0.19d	0.20d	0.28d	0.34d
12.0	0.13d	0.16d	0.19d	0.20d	0.27d	0.33d

In arriving at the ratio of moduli, it was assumed that the modulus of elasticity of mild steel was about 30 000 000, and that the modulus of elasticity of cinder concrete varied from about 800 000 to 2 500 000. y_1 is given for this range of moduli and for extreme fiber stresses on the concrete of 200, 250, 300, 500, and 650 lb. per sq. in. Thus, it will be found that Table 5 will cover values of y_1 for the ordinary assumptions for stone concrete, as well as for cinder concrete.

Thickness of Concrete.—Having the values of y_1, the carrying capacity of reinforced cinder concrete slabs for varying spans and varying loads can be tabulated.

Let W = total floor load, in pounds per square foot;
" L = span of slab between supports, in feet;
" M = bending moment from loading;
" R = resisting moment of slab.

Then, the bending moment (for simply supported slabs), in inch-pounds, coming on the slab is,

$$M = \frac{12\,W\,L^2}{8},$$

the resisting moment (Figs. 16 and 17) is:

$$R = M = 12 \times \frac{y_1}{2} f_c \left(\frac{2}{3} y_1 + y_2\right),$$

$$\text{hence, } \frac{W\,L^2}{4} = y_1 f_c \left(\frac{2}{3} y_1 + y_2\right) \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

For the outside spans of continuous slabs:

$$\frac{W\,L^2}{5} = y_1 f_c \left(\frac{2}{3} y_1 + y_2\right) \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

For slabs continuous throughout:

$$\frac{W\,L^2}{6} = y_1 f_c \left(\frac{2}{3} y_1 + y_2\right) \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

If $\frac{E_s}{E_c} = 30$, that is, $\frac{30\,000\,000}{1\,000\,000}$, and $\frac{f_s}{f_c} = 80$, that is, $\frac{16\,000}{200}$, then, for slabs simply supported (see values of y_1 and y_2 in Table 5):

$$\frac{W\,L^2}{8} = 24.57\,d^2, \text{ and}$$

$$d = 0.0713\,L\sqrt{W} \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

$$T = d + 1 \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Equations 5 and 6 are for the conditions shown in Table 8.

The values for d (and for T), the thickness of concrete slabs given in other tables, were derived by substituting the proper values of y_1 and y_2, in terms of d, in Equations 2 and 4, and reducing to Equations 5 and 6.

Of course, the thicknesses of the slabs, quantities of reinforcement, and carrying capacities are based on the relative quantities of concrete and steel. An excess of concrete or an excess of steel will alter the position of the neutral axis (Equation 1) and the carrying capacity.

In these calculations the working values of f_c, etc., are about one-quarter of the ultimate; that is, at a point in the stress-strain

TABLE 6.—THICKNESS OF SLAB AND QUANTITY OF STEEL REQUIRED WITH THE FOLLOWING LOADS, AND WHEN $\frac{f_s}{f_c} = \frac{16\,000}{300} = 53.3$; $\frac{E_s}{E_c} = 30$; $y_1 = 0.36\,d$; $y_2 = 0.64\,d$, FROM TABLE 5.

$d = 0.34\,l\sqrt{W}$ (W = load, in pounds per square foot; l, in feet). Weight of steel, in pounds = $0.204\,d$.

curve where the modulus of elasticity of concrete is supposed to be constant. If calculations are made for values about the elastic limit, then, according to some investigations, the moduli are variable in the concrete from the extreme fiber to the neutral axis, and the stress diagram would be somewhat like that shown in Fig. 18. With the latter assumption, the resisting moment is $12 \times f_c \times \frac{2}{3} y_1 \left(\frac{5}{8} y_1 + y_2\right)$, instead of $12 \times f_c \times \frac{y_1}{2} \left(\frac{2}{3} y_1 + y_2\right)$.

Quantity of Steel Reinforcement.—The force from the concrete (12 in. wide) resisting the bending moment due to the loading is $12 \times f_c \times \frac{y_1}{2}$; this belongs to a couple, and must equal the resistance of $f_s \times a$ in the steel. Hence, $a = 6 \frac{f_c}{f_s} y_1$, in square inches, or, in pounds per square foot,

$$a = 20.4 \frac{f_c}{f_s} y_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Substituting the values of y_1 and $\frac{f_c}{f_s}$ found in connection with each table, the quantity of reinforcement for each thickness of slab is derived.

TABLE 13.—THICKNESS OF SLAB AND QUANTITY OF STEEL REQUIRED WITH THE FOLLOWING LOADS, AND WHEN $\frac{f_s}{f_c} = \frac{16\,000}{650} = 24.6$; $\frac{E_s}{E_c} = 15$; $y_1 = 0.38\,d$; $y_2 = 0.62\,d$, FROM TABLE 5. THICKNESS INCLUDES 1 IN. FROM CENTER OF STEEL TO BOTTOM OF SLAB.

$d = 0.028\,l\sqrt{W}$ (W = load, in pounds per square foot; l, in feet). Weight of steel, in pounds = $0.315\,d$.

Excessive Concrete or Steel.—To note the effect of excessive concrete or of excessive reinforcement on the carrying capacity, observe y_1, Equation 1. Assuming the working stress in the steel to be constant, y_1, in Table 5, increases with an increase in extreme fiber stress and decreases with an increase in the modulus of the concrete. Some designers use cinder concrete with an excess of steel in order to keep the slab as thin as possible.

Example 1.—Suppose we are limited to a working extreme fiber stress of 250 lb. per sq. in., are designing for a total floor load of 150 lb. per sq. ft. on a 6 ft. 0-in. span (simply supported slabs), but wish to limit the thickness of the slab to 4 in. (3 in. effective depth).

In this case, the extreme fiber stress being fixed at 250 lb. per sq. in., and the ratio of moduli being assumed as constant at 30, the variable to be sought in determining y_1 is the stress in the steel. Suppose we use sufficient reinforcement to bring y_1 midway between the center of the steel and the top of the slab.

Referring to Equation 1, and substituting values for d (3 in.), m (30), and y_1 ($1\frac{1}{2}$), we have $\frac{3}{2} = \frac{3}{\frac{n}{30} + 1}$; but $n = \frac{f_s}{f_c} = \frac{f_s}{250}$; hence, $f_s = 7\,500$.

Therefore, in order to bring the neutral axis midway in the effective depth of the slab and not exceed 250 lb. per sq. in. in extreme fiber stress, the reinforcement must not be strained beyond an amount given by a stress of 7 500 lb. per sq. in. The weight of reinforcement in this case will be (Equation 7): $a = 1.02$ lb. per sq. ft. Now, with steel stressed to 16 000 lb. per sq. in., as assumed in Table 7, the total thickness of the slab would have been 5.3 in., but the quantity of steel would then have been only 0.44 lb. per sq. ft. Hence, 0.58 lb. per sq. ft. is required to save 1.3 in. in thickness of cinder concrete. With reinforcing steel at $2\frac{1}{2}$ cents per lb., the 0.58 lb. of excess steel will cost 1.45 cents per sq. ft.; and the saving effected will be 1.3 in. of concrete.

Example 2.—Suppose we have a 6 ft. 0-in., simply supported slab, and are using a cinder concrete having a working capacity of 250 lb. per sq. in. of extreme fiber stress (Table 7); and, for some reason, we wish to use a certain reinforcement, a little light in area, to take the tension at 16 000 lb. per sq. in. We are not allowed to exceed the 16 000 lb., and, therefore, must thicken the slab, to more than the normal thickness given in Table 7; that is, we must use an excess of concrete.

If the total floor load is 150 lb. per sq. ft., we find in Table 7 that the slab will be 5.3 in. thick, and the reinforcement will weigh 0.44 lb. per sq. ft. of floor.

Assume that the reinforcement we wish to use weighs only 0.36 lb. per sq. ft. We see by Equation 7 that a decrease in the section of the reinforcement may be effected by a decrease in the stress on the extreme fiber of the concrete. Therefore, looking in Table 8, which has a less extreme fiber stress, we find that, with a slab 6.2 in. thick, the reinforcement is 0.36 lb. per sq. ft. of floor.

If a less quantity of reinforcement had been desired, then calculations using lower extreme fiber stresses, similar to the calculations used for making these tables, would have been necessary.

Stresses in Approved Floor Slabs.—The location of the neutral axis for any particular thickness of slab is a function of the relative stresses in the materials, and of the moduli of elasticity. Referring to Fig. 7, assume that the ratio of moduli remains constant at 30, and that, $\frac{f_s}{f_c} = 64$, that is $\frac{16\,000}{250}$ or $\frac{20\,000}{312\frac{1}{2}}$, and that the slab tested is continuous; we find in Table 10 (the table using these assumptions) that the neutral axis is $0.32d$ from the top of the slab when the concrete and steel are proportioned for these stresses. For a 4-in. slab, therefore, the neutral axis would be 0.96 in. from the top of the slab. In Table 10, a normal 4-in. slab is good for a total floor load of 150 lb. per sq. ft. on a 5 ft. 0-in. span, with a reinforcement of 0.31 lb. per sq. ft.; but in this 4-in. slab, of 8 ft. 0-in. span (Fig. 7), as approved, No. 5 wires at 3-in. centers are used. This makes the actual reinforcement about 50% greater than the normal reinforcement for Table 10.

This relative excess of steel (reducing the comparative strain coming on the reinforcement) will lower the neutral axis below that given in Table 10. The strain on the steel, $\frac{f_s}{E_s}$, therefore, is in this case, $\frac{2}{3} \times \frac{16\,000}{30\,000\,000}$ (Fig. 16). Then, the neutral axis, on account of this excess of steel, will be located $0.41d$ or 1.23 in. from the top of the slab—instead of 0.96 in. where there is no excess of steel.

According to the ruling of the New York City Building Department, the 4 in. of cinder concrete weighs 32 lb. per sq. ft. of area. Therefore, the approval of this floor construction is for a total floor load of $250 + 32 = 282$ lb. per sq. ft.

Therefore, the bending moment, from this total load (if the slab is called continuous) is $\frac{W L^2}{1}$, or, 18 048 in-lb.

This is equal to the resisting moment (one force of the couple being $12\ f_c \frac{1.23}{2}$) having a lever arm, $\frac{2}{3} \times 1.23 + 1.77$ in., or $19.11 \times f_c$, in inch-pounds. Therefore, $f_c = 944$ lb. per sq. in., which

is the extreme fiber stress on the concrete. The area of the reinforcement being 0.134 sq. in., $f_s = 52\,000$ lb. per sq. in. in the steel.

If, instead of considering the slab continuous, we take an end slab,* as is done with stone concrete, we have a moment of $\frac{12\ W\ L^2}{10}$, or 21 658 in-lb. In this case the extreme fiber stress will be 1 133 lb. per sq. in., and the stress on the steel, 62 000 lb. per sq. in.

If we take the condition of reinforcement simply laid over the supports, as shown in Figs. 14 and 15, then the slab is simply supported at the ends, and the load moment becomes $\frac{12\ W\ L^2}{8}$, or 27 072 in-lb. This latter condition gives an extreme fiber stress of 1 417 lb. per sq. in., and a steel stress of 78 000 lb. per sq. in.

Of course, under such abnormal stresses the modulus of elasticity for cinder concrete, probably, does not remain constant, and the resistance diagram may assume a shape similar to Fig. 18. This would slightly modify the foregoing deductions. However, even if an indefinite number of assumptions were made regarding the ratio of moduli of elasticities of wire and of cinder concrete, ratios of stresses in concrete and steel, and the variable support of slabs, etc., the foregoing deduced stresses would still be found to represent approximately correct conditions.

Without further attempt to lengthen this inquiry (by considering an indefinite number of cases and conditions), the writer would call attention to the comparison of the thickness of stone concrete slabs with approved cinder concrete slabs under similar conditions. It is found that, for the same conditions as the approved cinder concrete slab (Fig. 7) discussed herein, the stone concrete would be required to be about 1 in. thicker than the cinder concrete.

Recommendations.—

1.—The practice of testing cinder concrete, arbitrarily, under the most favorable conditions, and then recommending the results of these tests to be used under the most unfavorable conditions which may exist in a building, is dangerous and entirely unnecessary.

2.—Unit stresses for the design of reinforced cinder concrete are of more importance for its proper use than the unit stresses

* Progress Report, Special Committee on Concrete and Reinforced Concrete, *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 385.

used for reinforced stone concrete, because of the greater variableness of the former.

3.—There are, at present, sufficient precedents for choosing some unit stresses for the use of reinforced cinder concrete slabs in each locality where this material is being used.

4.—It is practical, and of little cost for each city, to establish ultimately proper working stresses for reinforced cinder concrete, based on tests with the materials used in their locality.

5.—With cinder concrete used according to proper working stresses, the construction will be removed from the realm of mystification and of misrepresentation to the field of Civil Engineering.

CALIFORNIA PRACTICE IN HIGHWAY CONSTRUCTION.

By W. C. Hammatt, M. Am. Soc. C. E.

To be Presented May 20th, 1914.

Summary.

This paper describes suburban and country road conditions in California and the progress in road building in that State during the past few years. The State contains plentiful supplies of good road materials, rock, gravel, asphaltic oils, etc., and there are several cement factories.

The water-bound and oiled macadam roads are described and also concrete and asphaltic pavements; and details are given as to the good and bad features of the bases and the wearing surfaces. Some costs of asphaltic pavements are included.

With exceptional advantages in regard to road materials, California is, nevertheless, in its infancy in the study of road construction. Until about six years ago, practically no permanent road surfacing had been done outside of the municipalities. In the different counties some of the more important roads had been graveled, and a great many of the county roads had been oiled, but these measures

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

were taken more for the purpose of maintenance than as permanent construction work. The graveling was generally done during the rainy season in order to make the roads passable, and as the gravel was gradually worked down into the mud it was replaced by more until the depth of penetration of the surface water was reached, when the road became a good gravel highway. The oiling was generally done in dry weather, and the oil and dust formed a thin crust on the surface which was broken through by heavy traffic, and if not promptly repaired the road was soon impassable.

The southern counties of the State, which have ever been the leaders in public improvements, had expended some funds prior to the general awakening in 1908. These counties developed certain classes of cheap construction (to be described later), which, for a time, gave them an enviable reputation for roads. In 1908, however, the northern counties awakened to the need of better roads, and bond issues were passed in several of these counties for the purpose of putting permanent surfaces on their principal roads. The idea of a State highway system was developed in 1911, and, in 1912, a State Highway Commission was created and a bond issue of $18 000 000 was voted for the construction of a system of State highways.

Materials.

California is rich in many of the materials which go to make up the modern road. The Coast Range is prolific in trap rock. The Sierras are composed mainly of granite, though the foot-hills are of sandstone and shale; there are, however, in the foot-hills, a few quarries of good road rock. Gravel of a good quality for either road material or concrete, is found within easy distance of nearly every locality. There are four large companies manufacturing cement in the region of San Francisco Bay; mineral oil, with an asphaltum base, is obtained in eight different fields, distributed over about one-third of the State; and the largest refinery in the United States, producing asphaltum and asphaltic road oils, is located on San Francisco Bay.

Types of Road Construction.

Only the types of road surface used on country and suburban roads will be discussed in this paper, and each type will be taken up and described separately.

Water-Bound Macadam.—This type of pavement needs no description; it has been laid extensively in California, particularly about the centers of population. In many cases it has been laid to a finished thickness of as little as 4 in., in which case the coarsest size of rock is omitted, and the macadam is laid in two sizes only. It has been found that trap rock makes the best pavement, and that some of the softer varieties have the best cementing qualities. In fact, some of the best macadam pavements which the writer has ever seen have been laid with rock which would not pass the rattler test.

Where the sub-base has been properly prepared and drained, and the rolling has been thoroughly done, and where they have had the necessary sprinkling, macadam roads have stood up remarkably well even under automobile traffic. It is a deplorable fact, however, that the average road-builder underrates the necessity for care in the preparation of the sub-base.

Two facts are worthy of special note in the building of a macadam road: First, that a good macadam road cannot be built in rainy weather or when the sub-base is soft or wet from any other cause. To obtain proper cementation of the rock, there must be considerable resistance to the rolling. Second, the duration of the rolling cannot be specified in units of time per unit of area, as it depends on the nature of the rock and on various other conditions which make the judgment of the engineer in charge necessary.

Oiled Macadam.—This type of paving is peculiar to the localities producing an asphaltic oil. There is no fixed specification for its construction, but it is laid under many different ones, according to the whims of the engineer in charge. The name covers all classes of road surface in which oil is combined with road metal as a binder. The usual method of construction is to lay the road metal and roll the various layers in the same manner as for water-bound macadam, applying to each layer by a sprinkler a certain specified quantity of asphaltic road oil. In constructing this pavement, the main difference of opinion among road builders is in regard to the quantity of oil to be applied.

As a matter of fact, a very small proportion of the total area of oiled macadam pavement constructed has been successful. Under heavy traffic it ruts and waves very badly. It is the writer's opinion that, even under the best conditions, this pavement has little justifica-

tion. Oil has more lubricating than binding properties, and its introduction into a macadam pavement has a tendency to destroy the stability of the metal. The successful examples of pavements of this class have been either in localities where climatic conditions are such as to evaporate the more volatile parts of the oil, or where the application has been made in such a manner as to achieve the same result. Oiled macadam roads which have become so rutted as to be almost impassable, have been converted into fairly good pavements by scarifying and re-rolling, thereby aerating the oil and causing the evaporation of the lighter constituents.

Under this heading should properly come a patented pavement known as Petrolithic paving, which has been developed in the Southwest, and tried somewhat in other localities. It consists essentially of the incorporation with the natural soil of a certain definite proportion of rock and a certain quantity of oil, and the tamping of the mass into a crust, or pavement, by a roller containing spike-like projections which tamp the mixture from the bottom up. This pavement has been used with some success in localities where the soil is of a sandy rather than a clayey character, and where the summer temperature is high.

The cost of oiled macadam pavements, 6 in. in finished thickness, is about 75 cents per sq. yd., and that of Petrolithic pavements of the same depth about 60 cents.

Concrete Pavements.—Very little straight concrete pavement has been laid in California without a protective wearing surface. The writer knows of one experimental piece which has been laid with expansion joints, but it has been in use too short a time to be the source of any information at present. It was put down in two courses, the finish course being laid before the base course had set. The pavement is 6 in. thick, and cost about 90 cents per sq. yd.

In order to eke out an insufficient bond issue as far as possible, the State Highway Commission specified as the standard pavement, a 4-in. concrete base with a 1½-in. asphaltic wearing surface, and ordered that the base alone should be constructed at first, and either covered with a temporary coating of oil and screenings, or left unprotected until additional funds were available. Several hundred miles of this base have been laid, a large part of which has broken up into a series of slabs by shrinkage cracks, some of them being more

than 2 in. wide. One stretch, to the writer's knowledge, has gone to pieces by surface wear, but possibly this is due to poor concrete work which might have been prevented by better inspection. The cost of this base, inclusive of grading and what little protective coating has been used, has averaged 90 cents per sq. yd.

Asphaltic Pavements.—As might be expected from the fact that asphalt of a high grade is manufactured in California, the cities and suburban districts contain a high proportion of asphaltic pavements. The standard San Francisco pavement is 2 in. of sheet-asphalt on 6 in. of concrete. In the smaller suburban cities, this is modified to 1½ in. of sheet-asphalt on 4 in. of concrete. In late years sheet-asphalt is being replaced by so-called asphalt macadam, under the various specifications of Warrenite, Topeka specifications, etc. The concrete base often has asphalt macadam substituted therefor, and there is now a tendency toward the macadam base for asphaltic pavements.

As opinions differ largely as to the respective merits of the various classes of bases and wearing surfaces, the writer will merely give the results of his experience and his opinions derived therefrom.

Bases.

(*a*).—The concrete base has the disadvantage of a high shrinkage in setting and a large coefficient of expansion. The former causes the base to crack into slabs in setting and the consequent destruction of its monolithic quality. The latter causes a movement after the wearing surface, and, consequently, cracks in the latter. Another fault, which is one of general practice in construction rather than in the materials of construction, is that the concrete is generally laid in such a manner that the surface is gently undulating rather than absolutely uniform. This causes the wearing surface to be of varying thickness and subject to unequal movement, as will be described later under that heading. This can be obviated, however, by trimming the concrete base with a template while laying.

This base is the one most commonly used, due to a popular prejudice in its favor. Most laymen and many engineers cannot get away from the idea that a rapid chemical reaction will produce a substance more durable and serviceable than rock combined according to the laws of gravity and stability.

(*b*).—The asphaltic macadam base has not given good results, for the following reasons: It has no stability, but is subject to the same faults as the too-thick asphaltic wearing surface which will be described later.

In addition, asphalt in contact with soil has a tendency to promote vegetable growth, and many pavements of this class have been heaved up and broken from root growth, where, prior to the placing of the pavement, such growth did not exist.

(*c*).—A water-bound macadam base is the best for supporting an asphaltic wearing surface, for various reasons. It has a stability due to the seating of its component parts, which is not dependent on any chemical action. It has no movement under temperature changes. It is not rigid, and, therefore, does not give the destructive reaction to impact on the surface of the asphaltic pavement, which is a feature of the concrete base. The surface is free from depressions which vary the thickness of the asphaltic wearing surface.

Wearing Surface.

(*a*).—The limits of efficacious thickness of the wearing surface are quite small. The wearing surface must be thick enough to be held in position by its own inertia, as it has but small cohesion to the base; and it must be so thin that the compression of rolling shall be communicated throughout its entire thickness. It is inadvisable to make the wearing surface less than 1½ in., or more than 2 in., in thickness. Where the asphaltic wearing surface is laid to such a thickness that the compression is not communicated throughout the entire depth, the compression is not uniform, and the subsequent adjustment, which always takes place in an asphaltic mixture of insufficient density, causes inequalities in the surface which are starting points for failure by waving.

(*b*).—The quality of the pavement and the roughness of the surface are not dependent to any great extent on the size of the coarse aggregate. The best and most durable mixtures are those containing the highest proportion of fine aggregate of 80 to 200 mesh. If the mixture is laid hot enough, and the compression is properly done, the fine material, or "mortar", will come to the surface and thoroughly fill all the voids in the coarse aggregate, which then merely serves to decrease the quantity of asphalt necessary. The only way of obtaining

the rough surface so much desired by some, is either to have insufficient fine material to fill the voids, or to lay the mixture too cold or with insufficient compression. In each case, the wearing surface will be open and spongy. Also, if the coarse aggregate projects above the general surface of the pavement, the stones are crushed or rolled by steel tires passing over them, leaving voids where disintegration may start.

The costs of the various types of asphaltic pavement are as follows:

2-in sheet-asphalt, on a 4-in. concrete base.....$1.50 per sq. yd.
1½-in. Topeka specification, asphaltic wearing surface on a 4-in. concrete base.....$1.15 per sq. yd.
2-in. Topeka specification, asphaltic wearing surface on a 4-in. macadam base.....$1.10 per sq. yd.

The laying of an asphaltic wearing surface on an old macadam pavement, with no other preparation than the cleaning off of the fine material, has been done with great success. The cost of a 1½-in. Topeka specification wearing surface laid on old macadam is about 50 cents per sq. yd. All the costs given are based on labor and material costs prevailing in the bay counties about San Francisco.

Another matter worthy of note is the tendency of municipal governments in California to require street improvement work in the outlying districts to follow the same lines as in the thickly settled parts. Where the property is in large tracts, the villas have their own driveways, so that there is no occasion for teams or vehicles to stop in front of the property, nevertheless most of the municipalities require the placing of cement curbs and sidewalks, and the paving of the roadway from curb to curb, as in business blocks, thus spoiling the possibilities of architectural landscape work.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

HUACAL DAM, SONORA, MEXICO.

By H. Hawgood, M. Am. Soc. C. E.

To be Presented May 20th, 1914.

SUMMARY.

This paper describes the methods used in the design and construction of a concrete arch dam dependent on arch action for its stability. The dimensions of the dam are: crest length of curved structure, 140 ft.; radius, 76 ft.; maximum height, 100 ft.

The futility of attempting a determination of stresses by pure mathematical processes is discussed. It is pointed out that the lack of definite knowledge as to the behavior, under stress, of the rock in which the ends and base of the dam are intrenched, and to which it is joined, inhibits the application of pure mathematics, and the use of the simple formula for a thin cylinder is sustained.

For general information, and for comparative purposes, Table 1 gives the characteristic dimensions and stresses of numerous pure arch dams in various parts of the world.

The cost of the work is given, and there is also a description of the pipe line, conveying the impounded water from the dam to the place of use, together with its cost.

The works were executed in a difficult country, with impossible wagon roads, where the cement, sand, and some other materials had to be packed on animals, and where labor was disturbed by a state of war.

NOTE.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

The concrete dam described in this paper is an arched structure dependent on arch action for its stability. The use of the arch for dams and dependence on it for stability, is old; how old is not susceptible of proof, but certainly more than a century. Some time prior to 1800 was built the Meer Allum Dam, at Hyderabad, India, a multiple-arch structure composed of a succession of brick arches, varying from 40 to 82 ft. in radius, with an aggregate length of about ½ mile and a water depth of about 40 ft. A more recent Indian example is a dam 60 ft. high, also of the multiple-arch type, at Alwar, Rajputana. In Europe the Zola Dam, near Aix, France, of a radius of 158 ft. and a height of about 120 ft., dates from 1843.

In more recent years many arch dams have been built, notably in New South Wales and South Australia. Their characteristic dimensions are given on Table 1.

In the United States, the Bear Valley Dam, Southern California, built in 1886, has in the past attracted much attention by the boldness of its design, and yet its audacity is equalled by the less known Upper Otay Dam of the San Diego Water Supply, built in 1900. The granite masonry of the Bear Valley Dam was subjected to compressive stresses of about 61 tons per sq. ft., and the concrete of the Upper Otay Dam is subjected to stresses of similar intensity. The Otay Dam is an instructive illustration of the stresses which can be sustained successfully by a horizontal arch of Portland cement concrete, mixed 1:2.1:3.4, when founded and abutting on strong, hard rock. The advisability, however, of imposing such high stresses may well be questioned.

It is of interest to note that the old Bear Valley Dam, after doing duty for 27 years, has at last survived its usefulness. It has been superseded, and at high-water stages is submerged by the water impounded by a higher dam of the inclined multiple-arch type, designed and built by J. S. Eastwood,* M. Am. Soc. C. E.

The writer has not found any record of the failure of a true arch dam; if any have failed, it would be well to have all the facts brought to light.

It will be noted that the stresses sustained by the various structures have an extremely wide range, varying from a minimum of 10.6 tons to a maximum of 61 tons per sq. ft., or from 147 lb. to 870 lb. per sq. in.

* *Engineering News*, December 25th, 1913, Vol. 70, p. 1284.

After study of the available local materials and labor conditions, a stress of 16.3 tons per sq. ft., 226 lb. per sq. in., was adopted for the Huacal Dam. If labor experienced in concrete work had been available at Nacozari, a higher stress might have been considered. The most vigorous supervision cannot entirely eliminate the errors of uninformed labor; foremen, however competent, cannot be everywhere at once, and it is prudent to make allowance for probable inferior quality of the labor, an important factor in the proper placing of concrete.

The physical characteristics of the coarse aggregate enter largely into the question of allowable compressive stresses.

General.

The Huacal Dam was constructed during 1911-12 for the Moctezuma Copper Company, Nacozari, Sonora, Mexico (Phelps, Dodge and Company, New York), from the designs and under the general direction of the writer.

The purpose of the dam is to impound storm waters and create a gravity supply for the milling operations of the Copper Company. The water supply prior to the construction of the dam was obtained by pumping from the gravel beds of the Rio Nacozari. For a period of from 2 to 4 months of each year the waters of these gravels became so far depleted as to impose limitations on the output of the mill. The normal capacity of the mill is 400 tons of concentrates per day, and the required daily supply of water is about 1 250 000 gal. The pumping plant, now out of service, but held as an emergency reserve, consists of two 10 by 12-in. Aldrich triplex plunger pumps, electrically driven through gearing, discharging against a head of 225 ft. In round figures, the yearly cost of operating these pumps was $12 500. Decrease in cost and increase in water supply constituted the economic incentive for the dam.

Nacozari, the present southern terminus of the Ferro Carril de Nacozari, is 76.6 miles south of the International Boundary. The northern termini of the railroad are Douglas, Ariz., on the American side of the line, and Agua Prieta, on the Mexican side.

The dam is built across the canyon of Huacal Creek, about 3 miles northeast from Nacozari, at an elevation of 550 ft. above the town and 4 100 ft. above sea level. Nacozari formed the base of construction

h. Schuyler's "Reservoirs for Irrigation, Waterpower and Domestic Supply," p. 362.
The stresses, *S*, in Table 1, are computed by the cylinder formula:

$$\text{Stress, in tons (2 000 lb.) per sq. ft.} = \frac{\text{Radius (feet)} \times \text{Depth (feet)}}{32 \times \text{Thickness (feet)}}.$$

average cost of packing was about $1.02 per 2 000 lb. The cement was packed from the railroad depot, a distance of about 6 miles, and the sand from the Nacozari River, about 4 miles. The cost per ton-mile, one way, averaged about 21¾ cents.

All prices and costs are given in United States gold values.

Catchment Area.

The catchment tributary to the dam (Fig. 3) has an area of 13 sq. miles, is roughly rectangular in form, with an extreme length of 5.7 miles and a width of 3.4 miles. It is a mountainous area, broken by numerous watercourses with deeply incised channels. The slopes leading down to the channels are steep, vegetation is sparse, the soil shallow, with much bare rock, and the storm discharges are of a torrential character.

Rainfall.

The rains commence in June. May is a dry month, and the rain records are in the best form for comparative purposes when arranged by seasons running from June 1st to May 31st of the succeeding year. A rain gauge has been kept at Nacozari since May, 1910, but no definite information as to previous rainfall can be obtained.

TABLE 2.—Rainfall at Nacozari by Seasons.

Month.	1910-11. Inches.	1911-12. Inches.	1912-13. Inches.	1913-14. Inches.
June	0.51	2.66	1.17	0.08
July	4.39	3.73	4.66	4.13
August	2.32	2.25	3.59	2.77
September	0.89	4.79	0.00	
October	0.14	3.36	0.54	
November	0.33	1.38	0.83	
December	0.00	1.13	0.77	Highest rate of precipitation 3.05 in. in 3 hours, October 4th, 1911.
January	1.73	0.00	0.84	
February	1.43	0.31	4.52	
March	0.01	1.96	0.57	
April	0.60	0.20	0.53	
May	0.00	0.00	0.02	
Totals	12.35	21.77	18.04	

No gauges are maintained other than the one at Nacozari. The rainfall over the catchment area above the dam is unquestionably greater than at Nacozari, but to what extent is as yet purely a matter of estimate and conjecture.

Run-Off.

On the basis of the probable rainfall and the topographical features of the catchment area, it was estimated that the yield of a rain season such as 1910-11 would be approximately 3 000 acre-ft. (2 700 000 gal. per day). The season of 1910-11 was classed as "dry" by those familiar with the country. This opinion is supported by the rain records of

FIG. 1.—DAM SITE, LOOKING DOWN STREAM.

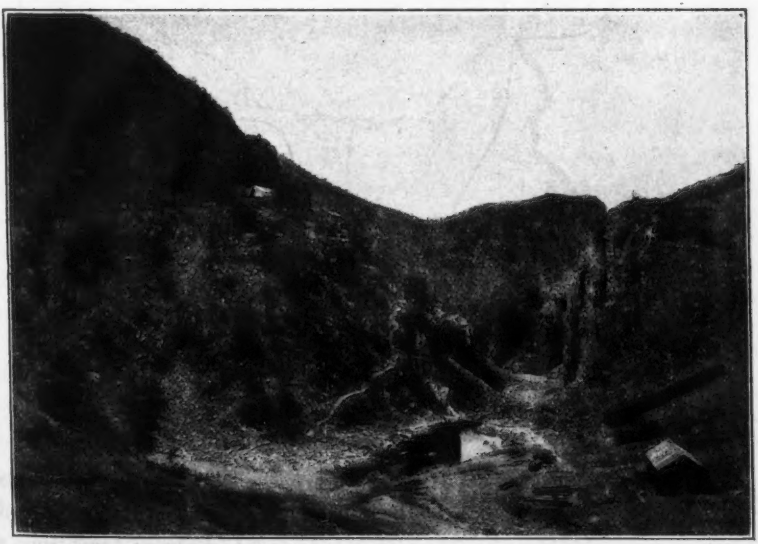

FIG. 2.—COMMENCEMENT OF WORK. LOOKING DOWN STREAM.

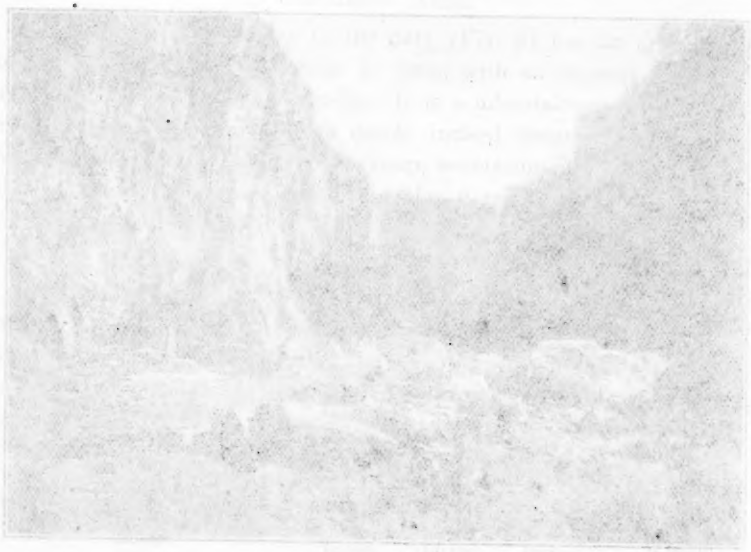

1911-12, 1912-13, as far as they go, but they are of too short duration to form any conclusions, and it cannot be assumed that there will not be drier seasons than 1910-11. The margin between the con-

templated use of 1 400 acre-ft. annually, or 1 250 000 gal. daily, and the 3 000 acre-ft., or 2 700 000 gal. daily run-off estimated for 1910-11 is considered ample to take care of drier seasons.

On August 14th, 1910, a storm run-off was observed lasting about 1 hour, the total discharge from which was estimated at 300 acre-ft., with an average run-off rate of 255 sec-ft. per sq. mile.

On October 5th, 1911, a flood, having a maximum rate of 2 000 cu. ft. per sec., passed, without damage, over the partly finished dam, then 40 ft. high. The total discharge during this storm was estimated to be 1 240 acre-ft., with a maximum run-off rate of 154 sec-ft. per sq. mile.

Reservoir and Dam Site.

In outline, the reservoir is T-shaped, as shown by Fig. 4. The dam and outlet of the reservoir are on the stem of the T, to each side of which the water surface at high water extends for about 1 mile.

The capacity of the reservoir at the crest level of the dam is 2 700 acre-ft., with a surface area of 93 acres. It is designed, should it be found desirable to impound more water, to install tumbling flash-boards along the crest of the dam.

At the point selected for the dam the canyon had in its natural state a bottom width of from 20 to 30 ft., and, at 90 ft. above the bottom, a width of 150 ft.

The geological formation is Andesitic. In the main, the rock is hard and close-grained. The dip of the formation approaches the vertical, and the strike is across the canyon approximately at right angles to its axis, both of which are conditions favorable to minimum leakage and stability of foundation. A seam discharging a little water was disclosed in driving the outlet tunnel and in the shaft beneath the outlet tower. During the active progress of the work it was impracticable to isolate and measure this water. In April, 1912, after the water in the reservoir had arisen against the dam to a height of about 40 ft., this spring was measured and found to yield 1.5 gal. per min. The entire flow over the rock bed of the stream at a point about 100 ft. below the dam was, on the same date, 3.58 gal. per min. This would ascribe a seepage through the dam and its foundation contact of 2.1 gal. per min. In February, 1913, 10 months later, the entire flow over the stream bed was again measured and found to have decreased to 2.83 gal. per min., the depth of water against the dam having in the interim increased from 40 to 60 ft.

The seepage through the dam and its foundation contact was not precisely segregated, but was judged not to exceed 1.0 or 1.5 gal. per

min. This trivial seepage speaks well for the care taken in making and placing the concrete, and in obtaining sound contact between the concrete and the native rock.

Design of Dam.

The narrowness of the canyon and the character of its rock sides and floor suggested an arch dam (Fig. 5) as the economic type for the location. Comparative studies with a rock-fill dam as a practical alternative confirmed the selection of the arch type.

The requisite cross-section of the dam was determined by the simple formula for cylinders subjected to external pressure:

$$\left.\begin{matrix}\text{Stress, in tons} \\ \text{(2 000 lb.) per sq. ft.}\end{matrix}\right\} = \frac{\text{Radius (feet)} \times \text{Pressure (pounds per square foot)}}{\text{Thickness (feet)}}.$$

The values finally adopted in the design of the dam were: Stress, 16.3 tons per sq. ft.; radius, 76 ft.; and the equation for thickness became $T = \frac{76}{16.3} \times \frac{D}{32}$, whence the thickness, T, at the depth, $D = 0.146\ D$.

With these values the theoretical triangular dam section has a vertical front face, and a back face on a batter of $1\frac{3}{4}$ in. to the foot. The lower portion of the dam is built of this form, the upper portion being widened to meet the practical necessities which govern a dam top.

The formula does not satisfy all the conditions, mathematically, for the dam is neither a complete cylinder with free ends, nor is it everywhere free to expand and contract; on the contrary, it is a segment connected at its bottom and sides with the immovable, but not the less elastic, country rock; and it is not a thin cylinder, but one of appreciable thickness. The problem is impossible of exact mathematical solution, for, however approached, its treatment is based on assumptions. The break of continuity in both form and material at the line of contact between the artificial structure and the natural rock, and the unknown value of the element of deformation in the natural rock, create uncertainties which, in themselves, render a mathematical demonstration based solely on absolute facts an impossibility, for the facts are not and cannot be known. Such elements of uncertainty are not confined to arch dams alone, they are equally prevalent with gravity dams. The researches and experiments of Pearson, Otley,

Brightmore, Baker, and others have shown the accepted middle-third method of gravity section design to fall short of being absolutely correct. Nevertheless, the fact remains that dams designed on that theory,

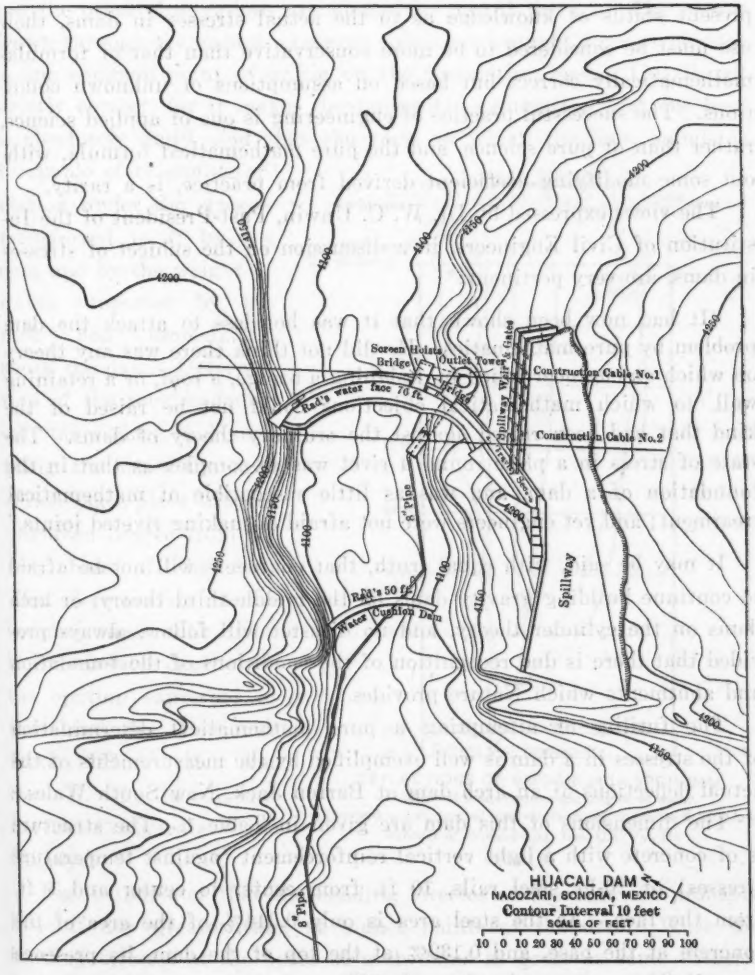

FIG. 5.

within certain recognized limitations as to intensity of stress, have been and continue to be successful. Similarly, the many Australian arch dams designed on the simple cylinder theory have been and continue to be successful.

Whatever the unknown and undeterminable stresses may be, particularly those around the foundations, the adopted formulas, empirical though they may be, have given and do give safe results, and, in the present status of knowledge as to the actual stresses in dams, their use must be considered to be more conservative than that of formulas mathematically correct but based on assumptions of unknown conditions. The successful practice of engineering is one of applied science, rather than of pure science, and the pure mathematical formula, without some modifying coefficient derived from practice, is a rarity.

The views expressed by Dr. W. C. Unwin, Past-President of the Institution of Civil Engineers, in a discussion on the subject of stresses in dams, are very pertinent:*

"It had now been shown that it was hopeless to attack the dam problem by pure mathematics. He did not think there was any theory on which an engineer relied in designing a bridge, a roof, or a retaining wall, to which mathematical objections could not be raised of the kind that had been raised against the ordinary theory of dams. The state of stress in a plate round a rivet was as complex as that in the foundation of a dam, and was as little susceptible of mathematical treatment; and yet engineers were not afraid of making riveted joints."

It may be said, with equal truth, that engineers will not be afraid to continue building gravity dams on the middle-third theory, or arch dams on the cylinder theory, and no disaster will follow, always provided that there is due recognition of the conditions of the foundation and abutments which Nature provides.

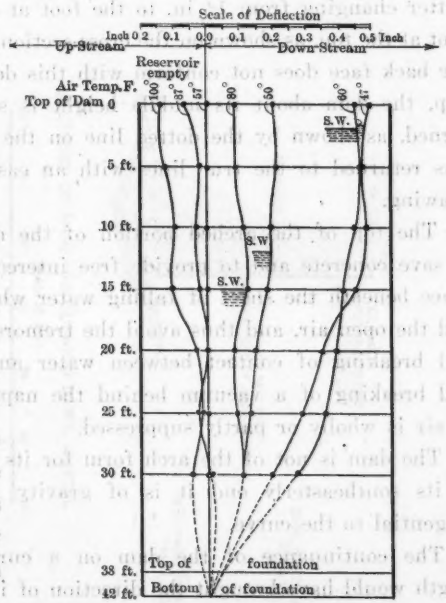
The futility of attempting a pure mathematical determination of the stresses in a dam is well exemplified by the measurements of the actual deflections of an arch dam at Barren Jack, New South Wales.†

The dimensions of this dam are given in Table 1. The structure is of concrete with a light vertical reinforcement (against temperature stresses) of 20-lb. steel rails, 10 ft. from center to center and 1 ft. from the face. As the steel area is only 0.044% of the area of the concrete at the base, and 0.139% at the top of the dam, its presence is negligible, as far as bending stresses are concerned.

The deflections of the Barren Jack Dam, which are shown in the diagram, Fig. 6, were taken under varying conditions of tempera-

* *Minutes of Proceedings*, Inst. C. E., Vol. 172, p. 156.
† *Minutes of Proceedings*, Inst. C. E., Vol. 178, p. 61.

ture and water depth. The observations made when the reservoir was empty and the air temperature 57°, which approximates the closest of the observations to mean temperature, are drawn as a straight line, and the other observations are plotted in regard thereto. The curves drawn through the various observed points are brought for convenience to one common point of origin on the foundation base. This is not strictly correct, for it makes the impossible assumption that the base is absolutely rigid, and that the rock on which the dam stands is incapable of elastic deformation under the stresses transferred to it by the dam and by the weight of water supported by the rock bed immediately above the dam. Deformation of the rock undoubtedly takes place, and, such being the case, the arch action takes place in some unknown degree from the very base of the dam. That deformation of the bed-rock does take place to considerable depths was the opinion expressed by the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E., in discussing the Coolgardie Water Supply.*



DEFLECTIONS OF BARREN JACK ARCH DAM
At different temperatures and heights of water.
Measured at 5-ft. vertical intervals from top of dam to 30-ft. below
Minutes of Proceedings, Inst. C. E. Vol. 178

FIG. 6.

Fig. 6 indicates that the bending stresses at the base are probably little if any greater than at higher points of the dam. Were the bending stresses at the bases of arch dams as great as some theories would lead us to think, many if not all the arch dams cited would have been fractured, and in particular the very thin dams of Bear Valley and the Upper Otay. That they have not been fractured is conclusive that the theories need amending.

* *Minutes of Proceedings*, Inst. C. E., Vol. 162, p. 123.

The extreme height of the Huacal Dam from base to crest is 100.25 ft. The foundation trench was excavated until sound rock was reached at depths from 5 to 15 ft. That there might be no powder cracks, hand tools only were used in the bottom of the trench. Similar precaution was exercised in the abutment trenches at each end of the dam, which were carried horizontally into the rock formation to a maximum distance of 20 ft. to insure contact with sound rock.

The front face of the dam is vertical, the back face has a variable batter changing from 1¾ in. to the foot at the bottom, to ½ in. to the foot at the top, as shown on the cross-section, Fig. 7. As actually built, the back face does not conform with this design precisely. By a mishap, the dam about its middle height is somewhat thicker than designed, as shown by the dotted line on the cross-section. The profile was returned to the true lines with an easy batter, as shown in the drawing.

The top of the arched portion of the dam is made hollow, both to save concrete and to provide free intercommunication between the space beneath the sheet of falling water when the dam is overflowed, and the open air, and thus avoid the tremors incidental to the making and breaking of contact between water and dam with the forming and breaking of a vacuum behind the nappe when the free passage of air is wholly or partly suppressed.

The dam is not of the arch form for its entire length. For 42 ft. at its southeasterly end it is of gravity section, and in direction tangential to the curve.

The continuance of the dam on a curve throughout its entire length would have brought the direction of its easterly end too closely parallel to the axis of the canyon to have been economical or safe.

In the canyon below the main structure there is a supplementary dam designed to create at times of overflow a water cushion with a maximum depth of 20 ft. over the base of the main dam.

Spillway.

No stream discharge records being available, the determination of spillway capacity necessary for safety became largely speculative and matter of opinion. The subject was studied in conjunction with D. C. Henny, M. Am. Soc. C. E., and after weighing all available data it was concluded that provision to pass a flood of 6 000 sec-ft. would

be ample. If this quantity is ever attained, 2 600 sec-ft. would flow over the top of the dam, and 3 400 sec-ft. through the spillway. Provision for a run-off of 6 000 sec-ft. from a catchment area of 13 sq. miles, or 452 sec-ft. per sq. mile, may be excessive, and there is some local evidence that such is the case; on the other hand, flood peaks of greater volume are not unknown in the semi-arid districts. The writer had occasion to make an exhaustive investigation of the Chase Creek, Arizona, flood of December, 1906. Chase Creek, a tributary of the Gila River, is about 200 miles north of Nacozari. Both localities have somewhat similar climates. The peak of the Chase Creek flood had a discharge rate of 647 sec-ft. per sq. mile from an area of 20 miles. The duration of the flood wave was about 40 min., with a mean rate of flow during that period of about 420 sec-ft. per sq. mile. The slopes of the country draining into Chase Creek are precipitous, averaging 1 100 ft. fall to the mile. The drainage slopes of the Huacal Basin are much flatter, and the channels less direct, consequently, the maximum discharge rate for the same rainfall will be less from the Huacal water-shed than from one of such abrupt topography as Chase Creek. Provision for 452 sec-ft. on the Huacal is probably more than the equivalent of 647 sec-ft. on Chase Creek.

The spillway discharge channel receives its water through nine openings regulated by pivot-gates. The aggregate effective length of the openings is 67.5 ft. These openings are separated from one another by 7-in. reinforced concrete partitions set at an angle of 45° with the axis of the spillway sill wall, and making an angle of 27° with the line of flow through the spillway discharge channel. Abrupt deflections of stream lines are thus avoided, and the capacity of the discharge channel is correspondingly enhanced.

The spillway gates hang on vertical pivots, which are slightly to one side of the center of the gate. The greater water pressure on one leaf of the gate than on the other, to the extent of the pivotal eccentricity, is used to make the gates self-closing and to keep them closed as long as the water level is below the danger mark. The automatic opening of the gates is accomplished by carrying the shorter leaf to a greater height than the longer one. A rise of water above the lower leaf will reverse the previous balance of pressure, and the gates will open automatically.

FIG. 8.—A QUIET DAY. LABORERS SCARCE.

FIG. 9.—A BUSY DAY.

Outlet System.

The discharge of water from the reservoir is effected by pipes controlled by flap-valves outside and standard screw-valves inside a concrete outlet tower, Fig. 10. The intake ends of the pipes are protected against trash by screens movable for cleaning.

The short bridge connecting the top of the tower with the dam is not connected to it rigidly. This leaves the tower free for independent movement in the event of an earthquake.

The gate-tower is a continuation of a shaft in the rock formation, from the bottom of which a pipe tunnel, in rock, runs out under the dam. The pipes consist of an 8-in. service pipe, a 12-in. blow-off, and a 10-in. drain. The tunnel is refilled with concrete in which the 12-in. and 10-in. pipes are embedded, together with an additional 10-in. pipe through which runs the 8-in. service pipe. This arrangement makes the service pipe removable for repairs or renewal. Should the other pipes rust out, the holes left through the concrete will answer all purposes.

The lower 8-in. intake pipe and the 12-in. blow-off are carried through a short tunnel into the tower-shaft. These pipes are of $\frac{3}{4}$-in. cast iron, embedded in the concrete of the tower. All these pipes are provided with the usual collars or flanges to stop seepage.

Cement and Sand.

The cement used was furnished, under the Standard Specifications of the American Society of Civil Engineers for Portland Cement, by the Southwestern Portland Cement Company, El Paso, Tex.

Tests at the dam, of neat cement, and cement and sand briquettes, gave the minima shown in Table 3.

The appearance and feel of the Huacal sand were not reassuring, but as the use of the local sand, if possible, meant a material reduction in cost, and as the cement and sand briquette tests promised well, a trial of the Huacal sand was made in a block of concrete containing some 80 cu. yd. The results were anything but satisfactory. After 10 days of setting a pick could be driven 1 in. into the mass without any great muscular energy. The total mass was removed, and the hope of using local sand was abandoned.

Good sand is always more or less scarce in arid regions, a fact largely attributable to insufficient natural grinding and washing to destroy and remove the softer particles. This is particularly true of locations such

as the one in question, where the greatest length from the dam site to the basin crest is 5 miles, a distance far too short to expose the rock detritus, in its journey along the various stream beds, to the scouring and abrading influences requisite to making good sand, however suitable the parent rock might be.

CONCRETE.

The writer's previous experience having shown a 1 to 2 mortar to be safe for water-tight concrete, and that a 1 to 2½ mixture bordered on the pervious, a proportion of 1 of cement to 2¼ of sand was adopted, giving an excess of about 25% of cement over the voids in the sand. The coarse aggregate was crusher run, graded from fragments of ¾ to 1 in. down to a coarse, sharp sand. The average of numerous tests gave the void spaces of the crusher-run aggregate, after compaction by shaking and jarring, as 38 per cent.

A series of tests was conducted to determine the proportion of sand to crusher run which would give a mixture of greatest density. These tests were made by progressive weighing of a box of known volume filled with the mix to be tested, the box being shaken and jarred during the process of filling. The greatest average weight was attained with 1 of sand to 2.03 of crusher run, the void space being 19 per cent.

The proportions actually fed to the mixers averaged 1 cement: 2 sand: 3.85 crusher run. The sand of the crusher run added to the

straight sand made the desired 1 to 2¼ mortar. The proportion of sand in the crusher run varied, of course, from time to time, with the wear and changing and consequent slacking and tightening of the crusher jaws. The foreman watched the composition of the crusher run closely, and from his observations adjusted from time to time the sand component so as to maintain practically constant the desired ratios.

The resultant mix gave a mortar approximately from 35 to 40% in excess of the voids in the coarse aggregate. Density of concrete was obtained with a sufficient surplus of mortar to coat thoroughly the surfaces of the 20-lb. to 300-lb. "plum" stones which were introduced as liberally as practicable. The "plums", first well wetted, were dropped into the mush concrete and worked around to insure liberation of any imprisoned air. The "plums" constitute probably 15% of the entire mass of concrete; a larger percentage would have been added if the hoisting facilities had permitted. The consumption of cement, as a whole, averaged about 1.3 bbl. per cu. yd. of completed concrete. Samples of finished concrete broken out of the actual structure weighed, dry, 152 lb. per cu. ft.

The concrete has proved to be water-tight to a marked degree, such slight dampness as appears in spots on the back face of the dam

being more probably due to seepage at over-night joints between one day's work and another than to percolation through the body of the concrete.

Plant.

The concrete plant was erected on the east side of the canyon at a higher elevation than the top of the dam. Cement was unloaded directly from the pack animals into store at the highest point of the plant, and the transportation was paid for by count of the sacks delivered. Sand, with transportation paid for by delivered weight, was unloaded and weighed into a bin near the bottom of the canyon and hoisted by bucket on inclined cable and delivered into gravity bins. The rock crusher was operated at an elevation corresponding with the spillway floor, and fed by rock from the spillway excavation. The product of the crusher was raised by belt and bucket elevator to the bins.

Cement, sand, and crushed rock gravitated from their respective bins to the batch-measuring hoppers, and thence to two mixers, one with a capacity of 12.7 cu. ft. to the batch, and the other of 21.7 cu. ft. The average composition of the mix was 1 cement: 2 sand: 3.85 crusher run.

The mixers delivered into a 1½-cu. yd. bucket slung between two standing cables, one crossing the canyon immediately below the dam and the other immediately above. Traveling carriages, one on each cable, moved in and out together. Hoisting tackle, independently operated, reached from each traveling carriage to the bucket bail. This arrangement permitted the depositing at will of the bucket at any point on the dam. Traveling and hoisting ropes were operated at speeds of about 600 ft. per min. light and 400 ft. per min. loaded. The maximum quantity of concrete placed in any one day was 114 cu. yd., and the average per day for the days on which the plant was running was 37.5 cu. yd. The minimum working time of mixing and placing 1 cu. yd. of concrete was 3.2 min., the maximum was 19.25 min. per cu. yd. (refilling outlet tunnels), with an average working time of 8.7 min. per cu. yd. for the whole work.

The machinery, picked up around the company's mines, and not without some incursions into the scrap pile, was of a heterogeneous character, incompatible with compactness or efficiency of operation. A saving in plant investment was effected at the expense of the constructional cost of the dam.

There were five steam boilers, ranging from 10 to 35 h. p. supplied with feed-water by a direct-acting, duplex, steam pump, drawing from water impounded above the dam. Six engines were used, a 25-h. p. for hoisting and a 30-h. p. for traversing the carriages on the cableways, a 26-h. p. on the rock crusher, a 30-h. p. on the sand hoist, and two 6-h. p. engines driving the concrete mixers. The fuel supply was chiefly wood from the live oaks cleared from the reservoir, liberally helped out with coal to compensate for the wood being green.

It would have been feasible to operate by electric current transmitted from the copper company's generating plant at Nacozari. This method was contemplated originally, but at the time was not deemed best. The experience of the work showed that the elimination of boiler and enginemen troubles and the elimination of transportation of coal, and other economies which would have followed with electricity as the motive power, would have resulted in a lower cost of construction.

The work was carried on during the Madero Revolution, when the country was in a state of turmoil; near-by collisions between the opposing forces were frequent, and the labor supply was disturbed and uncertain.

Forms.

The passing of any bolts, wire, or other form fastening, through from face to face of the dam was prohibited. The lower portion of the dam was constructed with wood forms of the customary stud and sheeting type, to a height above which the external struts bracing the studding would have become inconveniently long. The upper 60 ft. of the dam was built with steel forms (Fig. 11). These were in units 9 ft. wide for the water face and 8 ft. 3 in. for the back face, and 12 ft. high. They were generally used in threes, making a block space for pouring concrete 27 ft. by 12 ft. and of the width of the dam.

No attempt was made to vary the radius of the back face forms to conform to increasing radius due to decreasing thickness of dam with height. The forms were shaped to a compromise radius. The slight angle made by the adjacent forms, where not strictly conforming to the true radius, was imperceptible on the finished work. The location of the dam and its commercial use did not warrant the increased cost of forms of variable radius which would have been necessary for precision of shape. The front face of the dam being vertical,

its radius is constant. The front forms, being first set accurately to position, constituted a base from which were set the back forms.

The steel forms were supported by their lower edges engaging in hook-shaped projections on taper cast-iron plugs built in advance into the concrete as the work progressed. The plugs retained their position by virtue of being inclined downward into the concrete. After use, the plugs were withdrawn to be used again and the pockets were filled with concrete. Two plugs were used to a form unit, one under each corner. The plan proved satisfactory, except in some instances where the concrete bucket with its load struck heavily the top of the form and jarred the plugs loose. However, no instance occurred where the plugs actually let go. A bolt might be added to the plug, as shown by the broken lines on Fig. 11, which could be removed with the plug, the washer alone being lost in the concrete.

The walkway on top of the forms fulfilled admirably its purpose of a safe and convenient working platform for the concrete gang.

The forms were handled into place by the overhead cableways. The cost and time of removing the steel forms from set concrete and placing them in new position was low and in marked contrast to the cost and time of stripping the ordinary wooden forms. After the concrete work was completed, the steel forms were dismantled and part of their structural shapes and turn-buckles were used for the spillway gates. The remainder of the metal work was found useful, and absorbed for odd jobs by the mine mechanical department. There was but little material sent to the scrap pile, whereas with wooden forms there would have been practically no salvage.

Metal Reinforcements.

Both faces of the dam are reinforced vertically and horizontally against temperature stresses. The vertical members are old 12-lb. mining rails, 4 ft. 6 in. from center to center on the front face, and on the back face 4 ft. 6 in. from center to center for the lower 35 ft. of their length, and 9 ft. 0 in. from center to center for the upper 26 ft.

The horizontal reinforcement consists of five rings of 12-lb. rail immediately below the crest of the dam, and, from there down, $\frac{5}{8}$-in. round and square rods, with spacing varying from 15 to 18 in. from center to center.

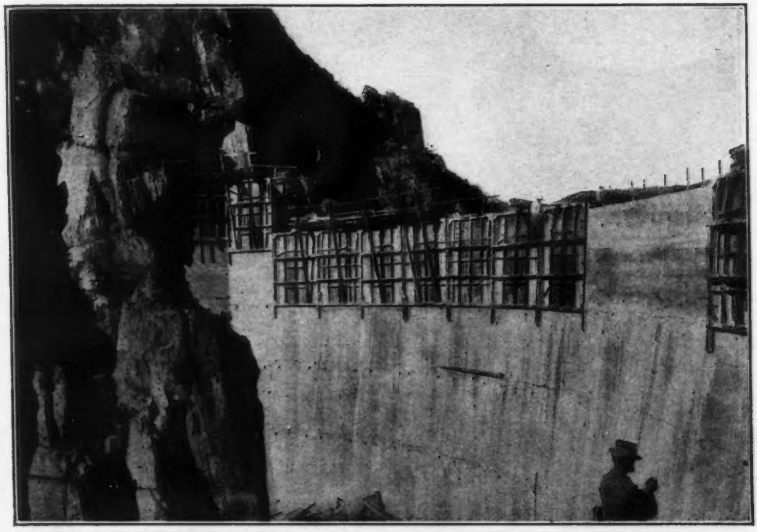

FIG. 12.—REAR FACE OF DAM, SHOWING STEEL FORMS IN USE.

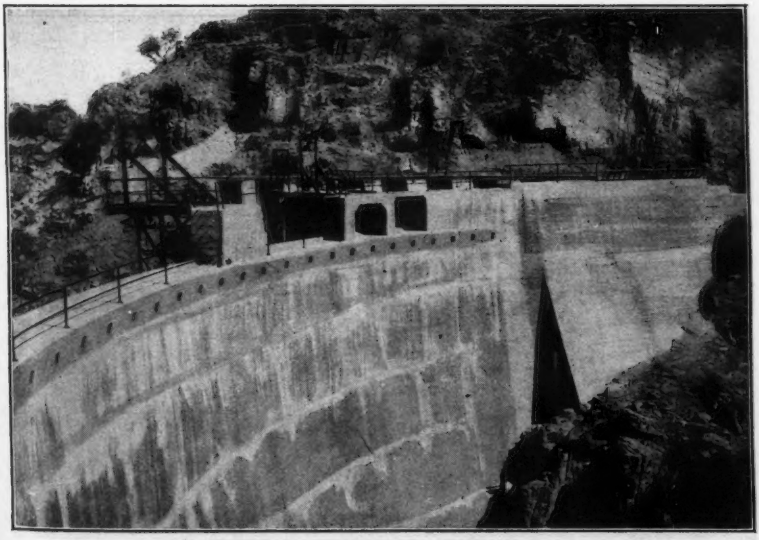

FIG. 13.—UPPER PORTION OF DAM, REAR FACE. GRAVITY SECTION ABUTMENT AT EAST END.

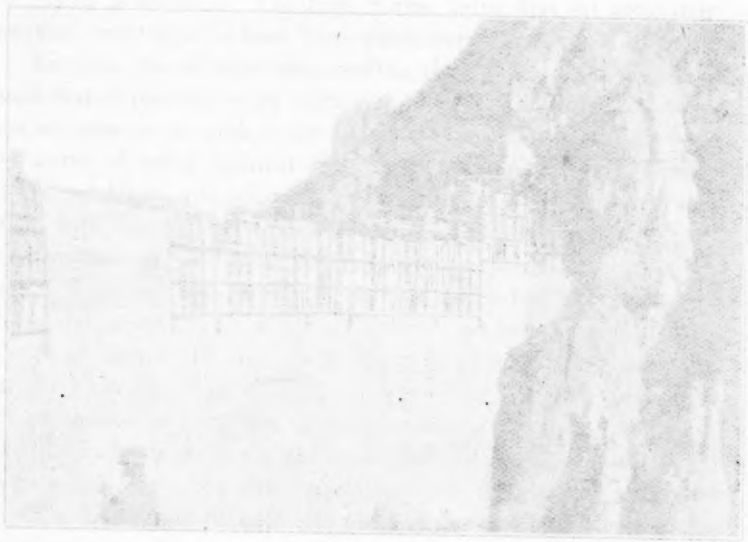

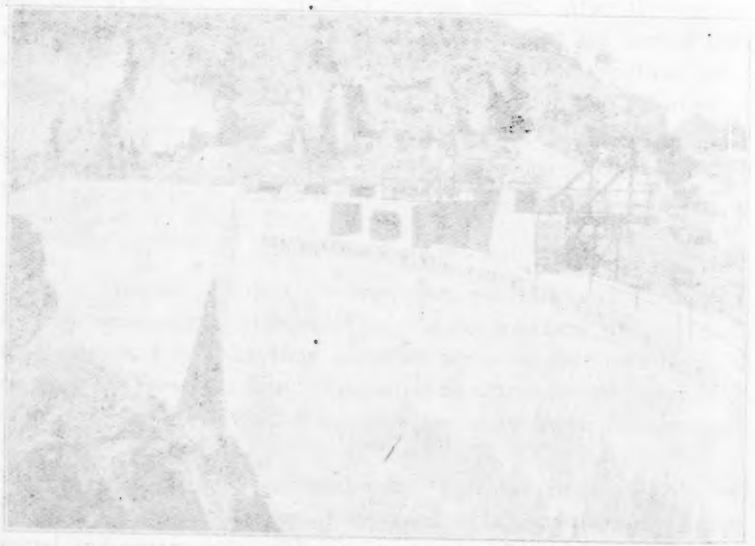

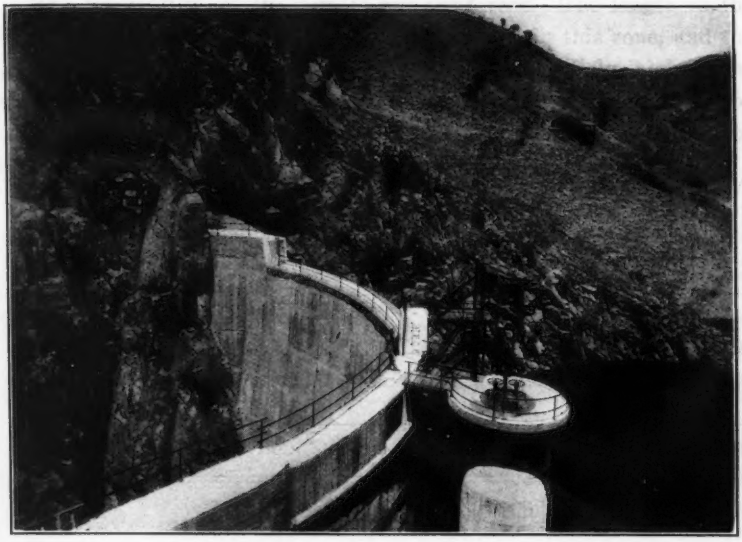

FIG. 14.—TOP OF DAM, FROM SPILLWAY.

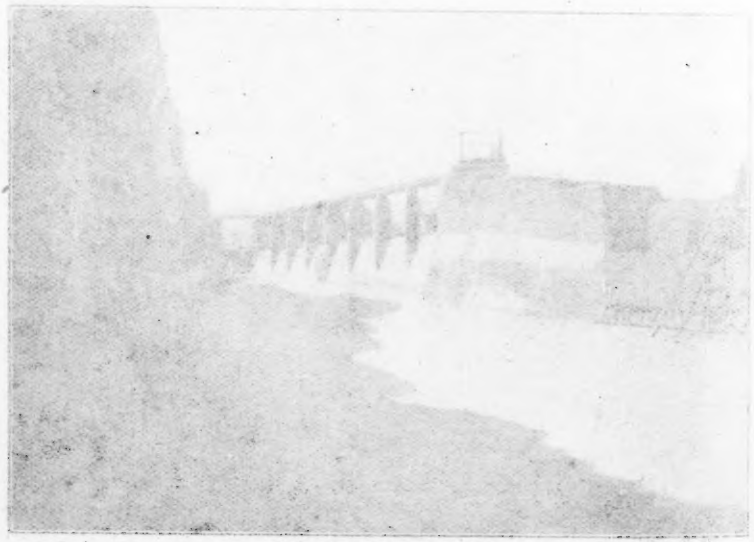
FIG. 15.—SPILLWAY. GATES NOT IN PLACE.



The lower 30 ft. of the dam is not reinforced. The length of the dam, measured on the arc, is comparatively small in this zone, and the possible temperature range is materially less than in the higher portions. Practically, the front face of the dam for this depth will be constantly immersed, which tends to uniform temperature. On the back face the lower part is less exposed to the sun than the upper.

PIPE LINES.

Water from the reservoir is conducted to the mill tanks at Nacozari through a pipe line, 2.91 miles long, composed of 1.13 miles of 8-in. and 1.78 miles of 10-in. steel riveted pipe, both of No. 14 gauge, furnished by the Lacy Manufacturing Company, of Los Angeles. Only on the lower 3 600 ft. of the line could wagons be used for the distribution of the pipe; for the remaining distance the pipe had to be packed by animals and men. Under these conditions, the savings to be made by using light riveted pipe outweighed considerations of permanency.

For wagon transportation, the pipe was made up in 20-ft. sections, and for pack animals in 10-ft. sections. Where buried in the ground, the usual California drive joints were used, and where exposed, flanged joints. The flanges are of pressed steel, riveted to the pipe. The flange dimensions were: for 10-in. pipe, 14¼ in. in diameter, 12¾-in. bolt circle, 12 ½-in. bolts; and, for 8-in. pipe, 12¼ in. in diameter, 10¾-in. bolt circle, 10 ½-in. bolts. When pipe had to be cut, or articulation was needed, bolted joints of the loose-ring type, with triangular rubber gaskets, were used. For water-tightness, the drive joints are dependent on the asphalt coating which the pipes receive in the final process of manufacture. In the field, after entering the end of the driven pipe, kerosene is poured around the outside of the joint and fired, and if necessary refired, until the asphalt coating softens and runs; then the

pipe is driven home. In straightaway work, a gang of experienced men can lay about 2 500 ft. of 8-in. or 2 200 ft. of 10-in. pipe in a day. When properly driven, and the pipe ends have not been deformed by transportation and handling, the percentage of leaky joints on testing out is very small. Leaky joints are remedied by galvanized-iron sleeves of sufficiently greater diameter than the pipe to leave an annular space of about $\frac{3}{4}$ in. into which neat cement or cement mixed with fine sand is rammed. When, from necessity, sleeves have to be put on a pipe under pressure, a closeable vent should be provided at the mid-length of the sleeve to discharge all leakage water until the cement sets. Seam leaks of minor nature are curable by floating fine sawdust through the pipe. With large seam leaks, it is preferable to put in a new section of pipe.

Break-pressure tanks of concrete, with "Davis" float-valve control, are introduced at two convenient points on the line, which limit the maximum static pressure to 179 ft. for the 8-in. and 283 ft. for the 10-in. pipe. At the summits, air relief and prevention of vacuum are afforded by 2-in. pipes carried up the mountain side to an elevation above the static head. The open ends of these pipes are protected by wire gauze to prevent the intrusion of foreign substances and living

things. Where the situation did not permit of open pipes, "Simplex" combined air relief and vacuum valves were used. The breakage of the pipe or the sudden opening of a blow-off valve at a low point in the line, thereby causing a partial vacuum, are to be particularly guarded against in light pipes. A vacuum which might be without ill effect in a heavy metal pipe line is absolutely fatal to thin riveted pipes, which have but little strength to resist pressure from without.

Test of Pipe Capacity.

Color tests of the velocity of the water traversing the pipe line were made by using permanganate of potash. Through 4 354 ft. of the 8-in. line, with a fall of 170 ft., the velocity was found to be 7.223 ft. per sec., from which the discharge was computed as 2.521 sec-ft.; the corresponding value of n in Kutter's formula is 0.0114. The velocity through 9 415 ft. of the 10-in. pipe, with a fall of 110 ft., was found to be 4.689 ft. per sec., and the computed discharge 2.555 sec-ft.; and the value of n is 0.0116. A volumetric test, made at the mill tank, gave the discharge as 2.529 sec-ft. In view of the fact that the pipes and tank were not calibrated, the three determinations of 2.521, 2.555, and 2.529 cu. ft. per sec. may be said to be in perfect agreement, the difference between the highest and lowest determination being but 1.33 per cent.

The writer takes this occasion to express his thanks to Mr. J. S. Williams, Jr., General Manager, and to other officers of the Moctezuma Copper Company, for their aid and co-operation in the work, and to Mr. C. A. Dodge for his effective supervision of the work of construction.

REINFORCED CONCRETE DOCKS: FOREIGN AND AMERICAN STRUCTURES. FAILURES, COSTS, AND GENERAL CONSIDERATIONS.

BY HARRISON S. TAFT, ESQ.

TO BE PRESENTED MAY 20TH, 1914.

SYNOPSIS.

During the past few years considerable discussion has taken place among engineers and chemists as to the feasibility of using cement in sea water, and the practicability and commercial success of reinforced concrete docks. In the United States the construction of reinforced concrete docks is in a very embryonic state, and the concrete of structures in sea water has not always been successful. On the other hand, concrete has been used successfully for more than 50 years in Europe for structures exposed to the action of salt water, and English engineers have been building reinforced concrete docks for about 20 years.

Part I of this paper contains a brief outline of the reinforced concrete dock problem as developed in Europe and Asia, the work in each country being examined. Part II reviews the art as carried out in the United States, both in sea water and fresh water. These two parts cover descriptions of reinforced concrete docks, as well as construction features of special interest.

NOTE.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

Part III takes up the subject of failures in past uses of cement in sea water in America, points out the reasons therefor, and brings out the fundamental principles covering the successful use of concrete in structures exposed to salt water and frost action. A foot-note calls attention to the chemistry of salt water, cement, and the use of concrete in sea water, in order to bring out discussion on this phase of the problem.

Part IV goes briefly into the question of the initial cost of reinforced concrete docks, as well as the cost of annual repairs.

Part V is a review of opinions of foreign expert dock engineers on the use of concrete in sea water and on the practicability of reinforced concrete docks; there is also a short review of the use of concrete in foreign breakwaters, closing with a few remarks as to the reasons for the success of foreign engineers in using concrete in sea water.

Part VI contains the writer's conclusions, wherein he cites the relative positions of English and American engineers in respect to the reinforced concrete dock question, and a more general use of concrete. He also speaks of progressive engineers possessed with the determination and courage to develop new ideas and uses for concrete, with due consideration as to previous failures, while conservative engineers still cling to old-time, long-established practices.

In the closing paragraph the writer calls the engineer's attention to the necessity of special training and knowledge for the successful execution of concrete structures in salt water.

The object of the paper is to make known to the Engineering Profession the exact up-to-date situation with respect to the development of this problem, the world over, the feasibility of using cement in sea water, and the practicability of building reinforced concrete docks.

Introduction.

In undertaking a study of the reinforced concrete dock problem, the subject has so many phases as to require a number of chapters to cover fully all the various ramifications into which it leads. From a world point of view, reinforced concrete docks are not a novelty. On the other hand, their practicability and commercial economy have perhaps as yet to be proven, especially in America. It is true that there are many reinforced concrete docks in successful operation in foreign countries, the most extensive development being found in England. As

their size and number are steadily increasing, it would appear that this class of dock construction has proved its worth, and sooner or later will become the standard type where a structure of a permanent nature is desired.

As reinforced concrete docks are somewhat of a novelty in the United States, it is perhaps necessary for engineers to seek the experience of foreign countries in order to obtain the necessary data on which to base their conclusions as regards the feasibility or otherwise of this type. Thus it is eminently fitting to investigate first what has been done in various parts of the world in the way of building such docks and the success accompanying such undertakings, and then discuss other phases of the problem, as to what precautions, etc., are necessary to render them a commercial, practical, and engineering success.

Part I.—Reinforced Concrete Docks in Foreign Harbors.

England.

In building reinforced concrete docks and other concrete structures in sea or fresh water, it is only natural that a forested country should be the last to take up the development of such a material. Consequently, America has been far in the rear in regard to this question, as compared with what other and older countries have accomplished. In England, France, Germany, Italy, and other European countries, in Australia, and in Asia, as well as in certain South American countries, concrete sea-walls, breakwaters, dry docks, piers, trestles, coaling stations, etc., in salt water, have been in existence for years. In looking up past undertakings along these lines, the writer was amazed to learn of the large number of reinforced concrete docks that have been built in foreign countries and the great success that has apparently been attained with them.

Southampton.—One of the most noted developments in reinforced concrete construction, as applied to harbor and dock development, is that of the London and Southwestern Railway Terminals at Southampton, England. The first and most prominent reinforced concrete structure in connection with this terminal was a coal barge jetty, 300 ft. long and 20 ft. wide, built in 1904, on the Hennebique system of driven concrete piles. The piles are about 44 ft. long, standing in 29 ft. of water at high tide, the rise and fall of the tide being about 13 ft. Each pile carries a maximum load of 17 tons.

This structure carries a very heavy traveling coal-hoisting apparatus for unloading coal from large vessels docked on one side, into harbor barges or scows which lie on the other side. Thus the jetty is subjected to constant blows from both sides, in addition to the heavy vibration due to the traveling machinery it supports.

In speaking of this jetty, Mr. Francis Wentworth-Shields, Dock Engineer for the London and Southwestern Railroad, says:

"Though the impacts from the vessels and scows cause this whole jetty to sway, there seem to have been no signs at the end of the first 2½ years of its existence of any of the concrete peeling off."

During recent years this dock or jetty is said to have shown some signs of deterioration, due to the vibration of the heavy machinery traveling along it, the supposition being that it was built too light in the first place to absorb the heavy vibrations to which it has been subjected. Still, the dock is said to have considerable elasticity. In one instance it was in heavy collision with a steamer, two piles and the beams they carried being broken. The dock was effectively repaired, but perhaps with some difficulty, though it is claimed that the repairs were easily accomplished.

The same railroad company has built several other reinforced concrete pile docks at Southampton, designed to carry the same heavy deck loads as the coaling jetty, but without the heavy vibration to which this jetty is subjected. Though built on the same system of construction as the coal jetty, the latter docks have shown no signs of wear or deterioration. It is said, on the best of authority, that they have cost nothing to date for maintenance.

The largest of these is the extension, on the Itchen Front, of "The Empress Dock", a widening of the so-called "Old Extension Quay" by a reinforced concrete pile structure, 50 ft. wide and about 1 300 ft. long, parallel to and securely dovetailed into the old quay wall. This widening dock is built of complete concrete bents, along the tops of which are steel deck-beams or stringers, which in turn are covered with 4 in. of wood, a wooden block pavement being used for the wearing surface. The depth of water at low tide at the face of this structure is 35 ft., which, with a 13-ft. rise and fall of the tide, gives a depth of 48 ft. at high tide.

One of the finest cold storage and cattle stations in existence was built at Southampton in 1905 to accommodate the foreign cattle trade.

The landing stage or jetty of this station is a reinforced concrete structure, 200 ft. long and 38 ft. wide, connected with the main land by two runways, 142 ft. long and 15 ft. wide.

On the opposite side of Southampton Harbor, at Woolston, on the Itchen, there is a reinforced concrete landing dock, 136 ft. long and 100 ft. wide, built in 1899 on the Hennebique system. This was the pioneer of reinforced concrete dock construction in Southampton waters. Up to date, this dock has cost practically nothing for repairs, except for damages due to the fact that it was rammed or otherwise damaged by a large steamer; it is in excellent condition at present. The cost of making the repairs is said to have been very small.

Up to the present time, it appears that at least six reinforced concrete docks, jetties, or quays, have been built in Southampton waters.

In building one of the Southampton docks, it is stated that some of the concrete piles were sprung out of line in driving them. A prominent American engineer reports that he saw a number of piles from 1 to 2 ft. out of line, but that they showed no signs of cracks. It has been stated that, in handling Chenoweth concrete piles, up to a length of 61 ft., and 13 in. in diameter, they were rolled about like wooden piles, at times having quite a spring in them. Under this treatment they showed a remarkable degree of elasticity and no signs of cracking.

Bending of Piles.—In discussing the bending of concrete piles, it is of interest to note a series of tests made on a hollow telephone pole in Fulham, London, England, in 1911. The pole was 44½ ft. long, 17 by 17 in. at its base (outside dimensions), tapering to 8 by 8 in. at its head. The thickness of the shell was 2 in., making the inside dimensions of the pole 13 by 13 in. at the base and 4 by 4 in. at the top. The vertical reinforcement consisted of 248 $\frac{3}{16}$-in. rods of high-tension steel, the ultimate tensional stress being from 80 000 to 85 000 lb.; 56 rods were grouped at each corner, 6 rods being spaced evenly on each of the four sides of the pole. The area of the concrete at the base was 106 sq. in., and the area of the steel 6.85 sq. in., a ratio of 0.0445. In making the test, the pole was set in 5½ ft. of massed concrete, with the pulling rope attached to its upper end.

In Table 1 is recorded the pull, in pounds, the deflection, and the permanent set after the loads had been released.

After applying the 6 000 lb., the test was discontinued for 3 days, and then the load was slowly increased to 9 200 lb., which gave a de-

flection of 66 in. and a permanent set of 21 in., with "cracks on tension side and permanent cracks more numerous and pronounced." There was no sign of failure on the compression side of the pole.

TABLE 1.—Test of a Hollow Concrete Pole at Fulham, England.

Loads, in pounds.	Deflection, in inches.	Permanent set, in inches.
300	¾	None that could be observed.
500	2	
1 000	4¼	
1 250	5	
1 500	6¼	
1 750	8	
2 000	9	
2 250	10⅛	
2 500	12	¼
2 750	14	¼
3 000	14¾	⅝
3 550	19½	¾
3 100	16½	⅞
3 500	18¾	⅞
4 000	22	¾
4 500	25½	1⅛
5 000	29	1¾
Load gradually increased to 5 750	34	Pulling wire broke. Pole flew back, vibrated short time and came to rest in vertical position with no permanent set.
Load gradually worked up to 6 000	37½	2 in. immediately after release of load. After interval of 1½ hours, set was reduced to 11/16 in.

Add to the above loads 100 lb. for weight of wire and recording apparatus, etc.

Notes on Behavior of Pile.—At 3 350 lb., slight hair cracks appeared on tension side at about 5 ft. 6 in. above foundation.

At 3 600 lb., slight hair cracks appeared at regular intervals about 6 to 9 in. apart.

At 4 100 lb., slight shear cracks appeared, starting at 33 in. above foundation and extending vertically, at a distance of 2 in. from tension side, for some 3½ ft. in length.

At 4 600 lb., hair cracks occurred regularly, 3 or 4 in. apart on tension side.

At 5 100 lb., cracks on tension side were noticed to be traveling across the sides of the pole to within 6 in. of compression surface.

At 6 100 lb., the shear cracks were more pronounced. The hair cracks on tension side were about 1 in. apart, but no signs of failure appeared on compression side.

The load was again applied. When a deflection of 73 in. was obtained, signs of failure appeared for the first time on the compression side, and the pole failed, but no record of the amount of the pull was obtained. The final examination showed that the pile failed equally for its entire length on the shear and tension sides, but without any local weakness. The compression side failed from the base up for a distance of about 2 ft. The bending moment at the base of the pile was reported to be 4 863 936 in-lb., a most remarkable test, which seems to substantiate the experience quoted above.

Liverpool.—The Mersey Docks and Harbor Board appears to have made a very limited use of reinforced concrete in its latest port develop-

ments, in spite of the extensive tidal and graving docks of concrete constructed at Liverpool. As a matter of fact, most of its first so-called reinforced concrete docks were in reality semi-concrete structures, that is, wooden piles carrying a concrete deck system. The oldest of these structures, the Cattle Wharf, Prince's Stage, was built in 1899-1901 on greenheart piles, with the usual Hennebique system of concrete deck-beams and slab. In addition to the Cattle Wharf, there are two other dock-quays in Liverpool, built on the same system, designed for a load of 3 tons per sq. yd., with a test load of 4½ tons.

Another of Liverpool's reinforced concrete docks is the Prince's Dock, West Quay, completed in 1905. This structure was designed to carry a super-load of 3 tons per sq. yd., or about 66 tons per pile. The piles are of concrete, 16 in. square, spaced 15 ft. 9 in. from center to center, across the dock, and 12 ft. 6 in. from center to center, longitudinally, and resting on rock.

At the west end of Liverpool's dock system is the so-called Brocklebank Dock, 226 ft. long and 64 ft. wide, a reinforced structure built in 1908 on the Hennebique system, and designed to carry the same loading as the Prince's Dock. The test load applied was 9 tons per sq. yd. The piles of this dock are 20 in. square, and had to sustain a load of about 95 tons each, when the test load was applied.

During the first year of its existence there was considerable trouble with the Cattle Wharf and other semi-concrete structures, due to the permeability of the deck-slab part of the structure. The dampness from the salt water entered the permeable concrete and attacked the steel reinforcement on the under side of the slab, causing pieces of concrete to fall off. The defect was overcome by applying a heavy coating of cement to the under side. The upper side of the deck-slab, which is washed daily, shows no signs of deterioration. This emphasizes the fact that great care must be taken in placing concrete in structures standing over or in salt water; there must be the closest inspection during their construction. As a result of this trouble, it appears that the steel reinforcement must be kept farther from the surface of the concrete in salt water concrete structures than in ordinary work. Whereas, at first a minimum of 1½ in. was supposed to be sufficient, the engineers of the London and Southwestern Railway have found this to be insufficient, and are now specifying a minimum of 2 in. for their new structures. Another difficulty encountered was the nu-

merous joints in the Liverpool system of dock construction. This appears to have been overcome by cleaning out the joints and filling them with a rich cement grout, with such success that the docks are reported to be in very satisfactory condition at the present time.

Thames River, Etc.—Within the bounds of the "Port of London Authority", and at other places on the Thames, many reinforced concrete docks or quays have been constructed. One of the most prominent of these is the Thames Haven Jetty Head, near the mouth of the river. This structure was built in 1908, for the berthing of large vessels, and is 136 ft. long and 32 ft. wide. It is supported by 19 columns or piers, 5 ft. in diameter up to low-water mark but of oval shape, 5 by 2½ ft. above. Each column rests on two 15-in. concrete piles of octagonal section, 45 ft. long, with a penetration of from 18 to 20 ft. After these concrete piles had been driven to refusal, a temporary iron caisson was put down over them. The reinforcing hoops were then lowered into place around the two piles and the caisson was filled with concrete. The caisson was afterward removed, being built in half sections.

Farther up the Thames, 20 miles from its mouth, is the Purfleet coaling jetty, built in 1904, a reinforced concrete structure, 250 ft. long and 34 ft. wide, carrying two heavy traveling cranes. The concrete piles are 14 in. square, from 40 to 50 ft. long, with from 15 to 18 ft. of penetration. The deck-slab is 5 in. thick. The jetty is connected with the mainland by a reinforced concrete approach, over which cars are run to the jetty itself. On one occasion this jetty was rammed by an 8 000-ton steamer, eight piles and 20 ft. of the decking being damaged. That the damage was not more extensive is said to have been due to the firmness of the horizontal decking. In repairing the dock it was necessary to withdraw the eight broken piles and drive new ones. In conducting this repair work, it was especially noticed that the steel reinforcing bars of the original structure showed no signs of rust, though it is well to note that the water at this point of the Thames may be brackish, and not real sea water. The repairs were efficiently made, and the quay is still doing duty.

Another interesting reinforced concrete coaling dock is at Dagenham-Essex-on-the-Thames, 10 miles below London, built in 1901. It is 780 ft. long and 35 ft. wide, and carries eight heavy traveling cranes, weighing 60 tons each, besides a railroad track. Each supporting col-

umn consists of three concrete piles encased in a concrete cylinder filled with concrete. Though it may seem a trifle odd, a careful study of photographs of this structure indicates that the tops of the columns are made with "capitals"—a well-proportioned and artistic structure as regards concrete dock work. A similar structure, known as the Prince of Wales Pier, was built in 1903 at Falmouth.

The Thames Iron Works and Shipbuilding Company has constructed at Dagenham a very substantial reinforced concrete dock, designed to carry a concentrated load of 60 tons, for the berthing and fitting out of dreadnaught battleships. In the construction of this dock, the Williams type of concrete piles was used for the first time. This type consists of an I-beam surrounded with $\frac{3}{16}$-in. wire, 12 in. from center to center, the whole being encased in concrete, with special provision at each end to take up the reaction of the driving.

In the same vicinity is the Hornchunk Dock and approaches, built in 1906. The main structure is 400 ft. long and 24 ft. wide, the approach being 280 ft. long and 16 ft. wide; both were built on the Hennebique system. The concrete pile bents are 14 ft. from center to center, braced diagonally and support a concrete beam and deck-slab system. Along the water-front side of this dock and its approach, a concrete curtain-wall was built between the piles. This curtain-wall in turn is protected by a wooden fender system. The plans seem to indicate that this structure was designed to carry a 27-ton crane in addition to a 27-ton locomotive.

A reinforced concrete coal dock was built in 1906 at Rochester, on "The Medway", a river flowing into the estuary of the Thames. This dock consists of a main water-front section, 32½ ft. wide and 340 ft. long, connected with the land by two concrete approaches, 100 ft. and 180 ft. in length, respectively. It was built on the Hennebique system, and carries a heavy traveling crane in addition to two railroad tracks. This was one of the first large undertakings in reinforced concrete dock construction on the Thames or its tributaries. At the time it was built it was looked on as the most important structure of its kind in England.

Though the exact number of reinforced concrete docks now in existence on the Thames or its tributaries is perhaps unattainable, it appears that they are more numerous in those waters than in any other part of England.

General.—Perhaps the largest reinforced concrete dock constructed up to date in England is at Swansea, on the southwest coast of Wales. It is a Hennebique design, almost 2 000 ft. long, completed in 1908, the whole structure being built in the dry. Some of its columns are 3½ ft. square. As this structure is used as a coal loading quay, and stands in 40 ft. of water, it is subjected to heavy loads and severe lateral shocks.

At the naval dock yard at Rosyth, Firth of Forth, Scotland, is found one of the most unique and interesting reinforced concrete docks or piers in existence. It is triangular in shape, 620 ft. long, has been finished recently, and forms the entrance pier to a tidal basin. The outer end consists of seven concrete monoliths with a mass concrete fill in the center, making a solid concrete head, 127 ft. long and 65 ft. wide, covering an area of some 8 300 sq. ft. The rest of the pier consists of twenty concrete monoliths, 25 by 30 ft., supporting a reinforced concrete structure consisting of girders, columns, arches, braces, and deck-beams. The upper decking consists of 3 by 10-in. creosoted wooden joists covered with a creosoted planking arranged so as to prevent any water from collecting thereon. It is a most massive and homogeneous structure, well capable of absorbing any heavy stresses it may receive from warships lying alongside.

In the Bay of Bristol, at Clevedon, where the tide has a rise and fall of some 49 ft., there is another interesting reinforced concrete structure, in the nature of a landing stage. It is 95 ft. long and rests on 22 reinforced concrete piles. The piles, extending up to low-water mark only, were driven through the marl until they reached hard rock. On top of these piles the reinforced concrete landing stage was erected, a structure consisting of columns, beams, bracing, and four different decks or landings.

A reinforced concrete dock of magnitude was recently constructed at Port Talbot. Being designed for coaling operations, it is subjected to heavy loads. The designed load was 850 lb. per sq. ft., the test load being 1 390 lb. per sq. ft., covering an area of 720 sq. ft. The outer row of piling consists of two 14-in. square piles encased in a concrete cylinder, 4 in. thick, and 4 ft. 6 in. in diameter. There are six such columns at the face of the dock. Each of the other two rows consists of eight 14-in. square piles. At this port there are also a number of similar structures, the first having been built in 1907.

It is of interest to note that one of the reasons which influenced the engineers in adopting reinforced concrete for the coaling jetties and wharves at Port Talbot Docks was an extensive fire in one of the docks, due to fuel oil which had escaped from one of the vessels. The oil was ignited through carelessness, and caused a very intense blaze over an area of about 250 by 50 ft. though, fortunately, the oil did not spread out under the wooden structures. With the world-wide use of oil as a fuel for the merchant marine, it is well to consider this danger in American wooden dock structures.

Although the Port Talbot Railroad and Dock Company was among the first to adopt reinforced concrete for wharf construction in England, and so was adversely criticized "for using an alleged untried material in such types of work", the results obtained have fully justified this radical departure from what was at that time the prevailing practice the world over.

Scattered all through other English ports are reinforced concrete docks of various sizes.

At Fleetwood, from 35 to 40 miles north of Liverpool, a reinforced concrete fish and coaling dock of considerable magnitude was completed in 1911. The fish shed section is 1 330 ft. long and 26 ft. wide, that is, the reinforced concrete quay part; the filled-in land behind the quay makes the shed sections some 70 ft. wide in all. The coaling section, of similar construction and carrying a coal-loading traveling crane, is 680 ft. long and 26 ft. wide.

At Harwich, 40 miles northeast of the Lower Thames, is the Parkeston Quay, a reinforced concrete dock structure more than 1 000 ft. long and 51 ft. wide.

On the northeast coast of England, at Newcastle-on-Tyne, a reinforced concrete jetty wharf of extensive size lies along the water-front of a large turret shop.

The port authorities at Dundee and Aberdeen, Scotland, are gradually replacing their worn-out wooden dock structure with reinforced concrete.

On the north coast of Scotland, at Ackergill, stands a life-boat slipway, 194 ft. long, built of reinforced concrete, extending out from the rocky shore into the wide open sea. There are several similar structures in other parts of Great Britain.

A reinforced concrete dock was built in the Shetland Islands in 1910. The head of this dock is 80 by 24 ft., and is reached by a concrete approach, 113 ft. long.

In Cork Harbor and other Irish ports reinforced concrete docks of considerable size have been and are being built.

At Portsmouth, Plymouth, and Cardiff are found the first reinforced concrete docks constructed in England, having been built previous to 1906. They are small, and are used mostly for coaling purposes. Quite extensive reinforced concrete docks, constructed during the last year or two, are found at Newport (Mon.), Swancombe, Gravesend, Portencross, South Bank, Ipswich, Newlyn, and numerous other places.

A number of small reinforced concrete docks or pier-heads, other than those just mentioned, exist in England in connection with shipyards, etc. Such docks are found at Dumbarton Shipyard, on the Clyde, and at several similar establishments.

At first the Hennebique system prevailed in all English reinforced concrete dock construction, but, of late, several other systems have been introduced, the most pronounced of these being the Considère spirally armored concrete piling. Though different types of piles are used in English reinforced concrete dock work, there is a most thorough system of diagonal bracing with each type.

In using the Hennebique or other systems of dock construction, where lateral and diagonal braces of reinforced concrete are put in the structure, it appears that trouble has arisen, and might again arise, from the joints in the bracing system. As the foreign docks built on the Hennebique and similar systems seem to have been a success, it does not perhaps cause as much trouble as it did at first, or would appear to cause. In a concrete structure, of whatever design, built in the water, there is always the danger of cracks below the water line, and these cannot be seen and properly attended to.

In a recent address, Mr. Robert Porter, of *The London Times*, stated that "England is one big port". From the vast number of reinforced concrete docks at present in her harbors, it does not seem amiss to say that some day soon the ports of England will be, figuratively speaking, one big reinforced concrete dock, and it will be impossible to enter that country without passing over a structure of this type. In fact, current English technical publications plainly indicate that there

is hardly a port of any prominence along her coast where reinforced concrete construction is not now being carried on extensively, to the extent of five heavy coal tip docks in one harbor alone, due to the great economy of such structures over their old wooden predecessors, in the way of maintenance expenses.

In a recent rebuilding of the old wooden docks or wharves at Plymouth, constructed 30 years ago, the engineers of the Great Western Railroad have stated that concrete construction was adopted because "the cost would be about two-thirds of the cost of rebuilding in timber." These new concrete docks rest on Considère piles, and were designed for a live load of 400 lb. per sq. ft.

In closing this description of English reinforced concrete dock construction, it is well to take note of a few points in favor of this type, as set forth by an English engineer from his experience in that field:

1st. Easy to build;
2d. Indestructibility;
3d. Small cost of annual maintenance; and
4th. Easy to repair.

Spain.

In Spain a number of interesting reinforced concrete dock structures have been built. At Seville, on the Guadalquivir, 50 miles from the sea, are two reinforced concrete ore-loading wharves of some magnitude. At the outer end of each a series of well-based columns supports an ore-loading car-tipping gear. The ore trains run over an extensive concrete viaduct to this tipping gear, and the ore is dumped from the cars by mechanical means into vessels lying at the head of each dock.

A rather striking reinforced concrete dock structure was built several years ago at Aznal Collar mines, also on the Guadalquivir River. It is 532 ft. long and 17½ ft. wide. Each bent consists of two piles capped with a deep concrete beam. As the bent piles are only 10.8 ft. from center to center, the deck system is cantilevered out about 3¼ ft. beyond the supporting piles on each side. The dock carries an electric traveling crane, the track of which runs along the outer edge of the cantilevered decking. The crane has a capacity of 11 tons at a radius of 39½ ft.

France.

In discussing reinforced concrete dock construction as carried out in France, it is of interest to note that the first reinforced concrete pile was made in France by the noted French engineer, M. Hennebique, in 1896, since which time the reinforced concrete pile industry has grown to vast proportions, being used extensively by almost every civilized nation on the globe. From the successful manufacture and use of concrete piling has grown the construction of reinforced concrete docks. Though reinforced concrete construction seems to have been of a negative nature during the close of the 19th century, except in France, its development, as applied to docks, was due to the influence and perseverance of M. Hennebique, and that too in a country other than France; thus reiterating the old saying that "a prophet is not without honor, save in his own country." The first use of reinforced concrete sheet-piling was made at Sable d'Olonne, Bay of Biscay, France. Though these piles were constructed in 1898, as a reinforcement to an old masonry sea wall, they are said to be in as good condition as when first placed.

To record the most important reinforced concrete docks in France: A concrete pile and retaining wall dock was built in 1902 at Nantes, on the Loire, 40 miles from the Bay of Biscay, and in 1912 was reported to be in good condition. At Arcachon, on the Bay of Biscay, not far from Bordeaux, the French engineers have constructed a reinforced concrete recreation pier, several hundred feet long, with some attempts at the artistic, to harmonize with the surrounding landscape. In constructing a quay type of dock at Dives, near the mouth of the Seine, concrete sheet-piles of the Coignet type were used. They are 7½ ft. from center to center, with a concrete slab closing the gap between them. This type consists of a pile with a sort of two-wing arrangement. A cross-section of the complete pile resembles a very flat T-beam. The piles are of 10 by 12-in. section, 26½ ft. long, and the wings are 5 in. thick, and of such width as to make the whole panel pile 4 ft. wide and 18 ft. deep, the pile part thus projecting about 8½ ft. below the panel part. This dock or quay is 190 ft. long. At Fecamp, 20 miles north of the mouth of the Seine, and exposed to the full sweep of the seas, there is a reinforced concrete dock, built in 1911 on the Hennebique system. The depth of water alongside the dock is 28 ft. at high tide. The dock is well braced by diagonal concrete struts, and

has a concrete deck-slab. Further to the eastward, near the Straits of Dover, at Boulogne, there is another reinforced concrete dock, built in 1906 in connection with a quay dock, the reinforced concrete section being 51 ft. wide and 1 050 ft. long.

As France is not a large maritime nation like England, the development of reinforced concrete docks there has not been so extensive as in some of the other European countries.

Holland.

At Ymuiden a reinforced concrete landing stage was constructed in 1903. It consists of two rows of hollow cylinders of reinforced concrete, 8 ft. 2½ in. in diameter and 28 ft. 8 in. in height, filled with sand. The rows of cylinders are 21 ft. 4 in. apart athwart the deck, but 16 ft. 5 in. longitudinally. The deck consists of the usual concrete beam, slab system, and carries two railroad tracks, being designed to support a 45-ton locomotive. The working face of the dock has a wooden fender-pile protection. With the exception of an extension of this landing stage, no other reinforced concrete dock work standing in sea water has been undertaken in Holland; however, extensive reinforced concrete quay walls, etc., have been constructed during recent years at Rotterdam, a fresh-water harbor on the Rhine.

Italy.

Though rather extensive use has been made of mass and reinforced concrete in the development of Italian harbors, etc., the writer has records of only two reinforced concrete docks built in that country. One is at Pozzuoli, near Naples, a regular Hennebique type of pile construction, with a heavy shear leg derrick at its outer end, and the other at Ravenna, on the Adriatic Sea.

Germany.

The overseas shipping of Germany is confined almost entirely to the two ports, Hamburg and Bremerhaven, the former of which is 85 miles from the sea, so that, compared with England, the number of reinforced concrete pile docks standing in sea water in Germany is exceedingly small. Although the port of Hamburg is equipped with the most modern shipping facilities, most of the docks are of the heavy masonry quay type, and not the long piers so common in America. This

is due to the narrowness of the Elbe as compared with the broad expanse of water-front of other ports. Although the writer's file is lacking in records of reinforced concrete pile or similar docks as having been constructed in Germany, no doubt they exist and are of considerable magnitude. It is hoped that some of the members of the Society may be able to furnish full information concerning them.

As to reinforced concrete dock construction in Sweden, Norway, Denmark, and Russia, the records are extremely meager, perhaps because there are no docks of this type in these countries. Russian engineers, however, have built several concrete docks in the Baltic Sea, there being one at Touapse, a jetty built of reinforced caissons.

Although little, if any, information seems to be available covering the harbor work, etc., of the eastern part of the Mediterranean, in Grecian, Turkish, and Asia Minor ports, it would be plausible to consider that the concrete industry is well known in that part of the world, and that it has been used to considerable extent in eastern Mediterranean ports as well as in the Black Sea, in the construction of not only graving or dry docks, but also reinforced concrete docks and quays.

Africa.

At Alexandria, Egypt, there is a reinforced concrete lighthouse, in 30 ft. of water, exposed to violent storms and heavy seas. Its base is a truncated pyramid 45 ft. high. The slender main tower extends some 33 ft. above the base, its top being about 48 ft. above sea level. At one time this lighthouse was rammed by a 3 800-ton steamer, but it does not seem to have been injured, except that, since that time, it has leaned 4° from the vertical.

At Senegal, on the French West Coast, a reinforced concrete pile dock and jetty was built in 1912. The dock is 242 m. (794 ft.) long, of varying widths, covering an area of 2 500 sq. m. (26 900 sq. ft.). The jetty head is 60 by 10.3 m. (196.8 by 33.8 ft.), with an approach 140 m. (461 ft.) long and 2.65 m. (8.7 ft.) wide, giving the jetty a total area of 1 300 sq. m. (13 990 sq. ft.).

At Cape Town, a long reinforced concrete pier was finished recently. The concrete pile part is 800 ft. long and 45 ft. wide, except for the outer 75 ft., where it is 65 ft. wide. The piles are 14 in. square, 200 being used in the structure. They were driven in groups of four, 13 ft. and 10 ft. from center to center, with a longitudinal clearance of

27 ft. and an across-dock clearance of 18 ft. between each group of four, thus enabling small boats to pass under the dock as well as down the center aisle, as it were. The outer 75 ft. is well braced, the piles being close to one another.

Australia.

Australia and New Zealand are far distant, and thus perhaps few data reach the American engineer as to their developments in concrete. From what is known of several famous concrete structures in that part of the world, these countries are well in the fore as respects reinforced concrete. In fact, at Auckland, New Zealand, there are from four to six reinforced concrete docks, two of which, at least, are of extensive size, *viz.*, a railroad dock, 1 500 ft. long and 240 ft. wide, and Queen's Dock, 1 200 ft. long and 280 ft. wide.

It is of interest, in passing, to take note of a reinforced concrete lighthouse standing in the Straits of Malacca, a two-story closed-in structure, supported by seventeen reinforced concrete piles. On top of the main structure there is an open part consisting of reinforced concrete columns and braces supporting the light and its house.

India.

At Madras three reinforced concrete docks, of the bulkhead type, were constructed in 1911. They consist of a series of concrete piles driven uniformly 8 or 10 ft. apart, depending on the type of construction used. Back of these piles were placed reinforced concrete slabs, in the same way that wooden planks are placed back of and secured to wooden timbers where bulkheads are built to retain earth.

In one type, where the water is only 6 ft. deep and the dock has a freeboard of 10 ft., 18-in. piles, 10 ft. apart, with a penetration of 18 ft., were used. The thickness of the two lower concrete slabs is 12 in., and that of the top slab 15 in.

In another type, where the water is 9 ft. deep and the dock has 6 ft. of freeboard, 15-in. square piles, 8 ft. apart, were used, the concrete slabs being 6 in. thick. The tops of the piles are connected by reinforced jack-arches. In the third type, the piles are 15 in. square, 10 ft. apart, and are tied back to anchors 30 ft. behind the face of the dock. The water is only 4 ft. deep at the face of the dock. Each of these three walls is about 1 500 ft. long, their total length being 4 700 ft.

China.

What is said to have been the boldest undertaking in the construction of a reinforced concrete dock is found at Shanghai on the Whang Poo River, 50 miles from the open sea. The great difficulty encountered in the building of this structure and its accompanying warehouses was the excessive depth of the overlying river silt. The design of the structure itself presents nothing especially new, in comparison with other dock structures, as built in England. The fact that nothing but mud of various degrees of solidity, with layers of impure sand at irregular depths and a thin layer of gravel at a depth of 300 ft., covered the location of the proposed structure for a tested depth of 400 ft., gave a most unsatisfactory soil on which to construct a dock. At a depth of about 400 ft. there was a bed of gravel. The top layer of 25 ft., into which the concrete piles were driven, consisted of a solid crust of stiff sandy clay crossed with old creek beds filled with soft mud, rendering the surface somewhat irregular. The load on the piles had to be carried by the skin friction of this upper layer of supposedly firm ground. From a careful study of the situation, and from deduction obtained from old timber docks built in the same soil, a factor of 500 lb. per superficial foot of pile was fixed as the maximum carrying capacity of the piles, exclusive of their own weight.

The dock structure is 1 160 ft. long and 174 ft. wide, the rear 160 ft. being covered with two steel-frame sheds arranged in such a way as to leave an open space of about 250 ft. between them as an entrance way to the main office building. The decking of the dock was designed for a load of 500 lb. per sq. ft., with a deck load of 350 lb. per sq. ft. for the general structure. In general, the structure consists of a 5-in. deck-slab, deck-beam, and girder system of concrete construction, carried by 15 by 15-in. concrete piers, 15 ft. from center to center, each pier being supported by four 14-in. square concrete piles. At the face of the dock, where there is a large traveling crane, the columns are 18 in. square, and are carried by a group of six 14-in. square piles. The designed load per pier was 45 tons, or 11 tons per pile. The structure has the usual horizontal, cross, longitudinal, and diagonal bracing ties.

Due to the extraordinary conditions under which this dock was built, it is of interest to note a few facts as regards the pile-driving and the final loads carried. The piles were driven with a 3½-ton steam

hammer, the weight of the cylinder, which acted as a dead load on the pile during driving, being 1½ tons. The piston stroke was from 6 to 8 in. The piles had a penetration of about 25 ft., the final set being 1 in. under the last blow. It is stated by the engineer of this structure that "no anxiety was felt as to the future stability of the majority of the piles" under such an excessive set, as it was considered that their supporting power would be increased after the skin of water between the mud and pile had escaped and true skin friction was established. The resistance to driving increased very little after a 15-ft. peneration had been reached, and sometimes was less for a penetration of 25 ft. and above. On one occasion the piles sank so rapidly under the imposed dead weight of the hammer and cylinder that their descent had to be checked by holding up the dead weight of the hammer at the desired elevation. After 4 weeks, this group of four piles was tested with a load of 45 tons, and there was a 1¾-in. setting in 2 weeks, when the settlement ceased. The piles were lengthened 8 ft., and then driven deeper. Though it took 80 blows to re-start the piles, they were finally driven with the same ease as at first. A subsequent test of 45 tons gave a settlement of 1½ in. No additional attempts were made to lengthen any of the piles. When completed, the dock was loaded to more than that for which it was designed (1 000 lb. per sq. ft., by mistake), with no sign of any settlement.

In general, the piles were from 6 to 8 weeks old before they were driven. The range of temperature was about 150°, which appeared to cause hair cracks in winter along the lines where work was stopped in the deck-slab. One of the leading dock engineers of England has remarked that this dock illustrates the great advantages of a concrete decking in its ability to distribute the superimposed loads and thereby assist the piles to carry a heavy burden. The larger part of this structure was moulded on land and put in place on the unit system, as it were, especially those parts below water, except the caps. In connection with this dock, there was also built a quay wall about 495 ft. long and 21 ft. wide, on one side of the property, for the berthing of lighters.

Japan.

The writer has no record of any reinforced concrete pile docks having been built in the development of Japanese harbors, yet he has no doubt that they exist. For 20 years, at least, the Japanese have

been using concrete in breakwaters to an enormous extent, and it is only a part of wisdom to consider that they have used it in other reinforced concrete structures in sea water. Recently, extensive developments have been made in the harbor of Kobe, where four concrete piers have been built, and of a most unique type of construction, *viz.*, reinforced concrete caissons built in the dry on a pile structure on the shores of the harbor, then lifted off this foundation by a specially designed depositing dock, carried into deep water, and put afloat by sinking the depositing dock and withdrawing it from beneath the concrete caissons. The caissons were then towed to and sunk in their proper places in the quay wall. Each caisson, 119 ft. long, from 35½ to 41½ ft. high, and from 24 to 30 ft. wide, has twenty open-top cells, and weighs from 1 900 to 2 400 tons.

Philippines.

It may not be exact to regard the Philippines as a foreign country, so far as concerns engineering work now being done, yet, in this paper, it has been classed as such, and note is here made of the reinforced concrete docks in those waters. The first dock of this type was built in Cavite at Manila in 1902, on what is known as the "Cushing System of Piers", *viz.*, cast-iron cylinders surrounding wooden piling and filled with concrete, the deck system consisting of steel girders and beams covered with a concrete slab. The dock is 408 ft. long, 75 ft. wide, and contains thirty-six cylinder piers 6 ft. in diameter. The structure was built by the United States Navy Department in connection with a coaling station.

Two docks of a similar design were built in 1906 by the Navy Department at Manila. One of these is 650 ft. long and 110 ft. wide; the other is 600 ft. long and 70 ft. wide. There are nearly 300 cylindrical piers in the two structures.

The Navy Department has also constructed two reinforced concrete docks at the Naval Station, Olongapo. One of these is 332 ft. long and 45 ft. wide; the other is 300 ft. long and 60 ft. wide. The piers or columns of both consist of hollow concrete cylinders, 2½ ft. in diameter, filled with concrete, and 12 ft. apart longitudinally and 18 ft. transversely. The decking consists of I-beams, encased in concrete, and these support a suitable concrete slab. There are light diagonal ties at each bent, running from the base of each outer column to the

top of each inshore column, but there does not seem to be any other lateral bracing.

Another reinforced concrete dock has been finished recently in the Philippines, at Iloilo, about 330 miles south of Manila. It runs along the face of an old sea wall, and consists of a series of transverse girders, 10 ft. from center to center, with a 12-in. concrete deck-slab. The outer end of each girder rests on a hollow cylindrical column, and the land ends are seated on a concrete pedestal built up from the natural slope of the bank. At the face of the wall, arches are inserted between the girders in order to provide additional strength to resist lateral stresses, as well as to give to the dock an artistic finish.

South America.

In view of the extensive harbor developments and the magnificent systems of docks, etc., in some of the ports of the leading South American countries, it is to be regretted that more general information concerning them is not readily available for the engineers of the United States. These engineering undertakings and port developments stand out as the most prominent of such world undertakings, especially at Buenos Aires, which city is conceded to have the finest shipping and port facilities in the world, with Montevideo a close second. It has been stated that almost all South American docks of any magnitude are being constructed of concrete, though the percentage of reinforced concrete structures among them is unknown to the writer.

In the foregoing the writer has attempted to outline the most important concrete docks, etc., constructed up to date in European and other countries, without any attempt to go into the technical side of their design, though some of them are more in the nature of semi-concrete and concrete steel docks than full concrete structures. The list is far from complete, but gives a general idea of the extensive use of reinforced concrete in dock construction in foreign ports.

Part II.—Reinforced Concrete Docks in the United States.

In recording what has been accomplished in the construction of reinforced concrete docks in North America, including Porto Rico, Cuba, the Canal Zone, and Canada, such undertakings are so few and of such recent date, compared with those in European countries,

that the art of building reinforced concrete docks there may be said to be hardly beyond its infancy, especially as regards out-and-out docks or piers, as the American usually understands the word, *viz.*, long structures running out from the shore in such a way that vessels can lie on each side. Unfortunately, it will be necessary to make note of some failures among North American concrete docks.

Atlantic Coast.

Boston.—The first concrete dock built in Boston Harbor has perhaps caused more discussion as to the feasibility of using concrete in sea water than any other American structure of this type, and, therefore, is far-famed in itself. This dock, or pier, was built at the Charleston Navy Yard about 14 years ago. The first section, consisting of a long, straight wall, was built in 1899-1900, without any resort to a coffer-dam. The other two sections, consisting of plain reinforced arches, 20 ft. wide, with spandrel walls, were constructed in 1901, the space between the two walls being filled with earth and stone. The first section was built of 1:2:3 concrete throughout, and it was all placed in the wet, with an open-top bucket. The second and third sections were of different mixtures, the main body being of 1:3:6 concrete, the outer 2 ft. consisting of a 1:2:4 mixture, and the whole exposed surface was faced with 3 in. of 1:1 mortar. In these two sections the concrete was placed very dry, as was the practise at that time.

During 1913 one of the Boston public docks, Pier No. 5, was partly rebuilt in concrete. This dock consisted of a timber platform deck, 50 ft. wide and 1 150 ft. long, on each side of a solid earth fill. The new wooden piles needed were driven, and all the piles, new and old, were cut off at mean high water and capped with a deep reinforced concrete beam running athwart the piles, in the way of curtain-walls. These curtain-walls support two longitudinal reinforced concrete beams, the third or inner beam resting on the earth retaining wall. There are also two additional concrete beams under the track along the outer face of the dock, with special supporting piles. On top of the curtain-wall and longitudinal girders is laid a reinforced concrete floor-slab with a 2-in. bitulithic top. Wooden longitudinal tie members are run from top of pile to top of pile under the concrete curtain-walls, the whole timber structure being well braced with piles and wooden ties. To provide against accident from disintegration

of the lower part of the curtain-walls, due to frost action or other cause, cast-iron columns, 30 in. long, are attached to the top of the piles and made integral with the curtain-walls, thus guarding against weakness in the concrete, rather than in the piles, as done in other harbors.

New York Harbor and New Jersey Coast.—A reinforced concrete dock of an experimental nature was constructed at Ellis Island, New York Harbor, in 1911. It is a rather small structure, 30 ft. wide and 50 ft. long, resting on thirty-six driven concrete piles 18 in. square. The piles were made of different mixtures, for experimental purposes, and various kinds of water-proofing were used in order to determine their efficiency under the same conditions. This was the first complete concrete pile and deck dock built in New York Harbor.

During the past seven years a semi-concrete type of dock has been under development in New York Harbor, *viz.*, wooden piling, wooden caps, and concrete decking. In one dock, on the New Jersey side of the Hudson, the caps on top of the piles are also of concrete. In the final type, as worked out by the Department of Docks and Ferries,* the concrete slab rests directly on wooden caps secured to the tops of the wooden piles, a genuine flat slab between bents, the entire timber floor system being wholly eliminated. At present some 25 or 30 semi-concrete docks have been built on this system in New York Harbor. It has been stated authoritatively that they have proved a great success.

In building two semi-concrete docks at the Brooklyn Navy Yard a few years ago, the objectionable features of docks of the foregoing type—*viz.*, part of the wooden pilings and bracing exposed to wet and dry conditions between low water and the decking, and the wooden cap as an additional temporary item helping to support a permanent structure—were eliminated. In the two Navy Yard docks the wooden piles were cut off a little above low water and capped with a wooden grillage. Pre-moulded concrete columns, mixed with water-proofing compounds, were set on and dovetailed into the caps, and a concrete girder-beam and deck-slab system was worked over the tops of the columns. The wearing surface consists of a creosoted wooden block pavement. Down each side of the dock there is a standard-gauge railroad.

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 503.

A small concrete dock was constructed at Glen Cove as a yacht-landing, in the winter of 1909-10. It consists of eight reinforced concrete rock-filled caissons, supporting an overhead footbridge, the total length of the pier being about 330 ft.

Long Branch.—At Long Branch a Hennebique type of concrete pile dock was constructed in 1911, running some 848 ft. out into the Atlantic Ocean, as a boat landing and recreation pier. At present the pier is only 75 ft. wide, except for an 80-ft. length at its outer end, where its width is 150 ft., the intention being to make the whole pier of that width at some future time. The deck is 22 ft. above low water. The piles are 16 ft. from center to center longitudinally, but 20 ft. from center to center across the pier, except the outer two rows, which are 15 ft. from center to center. Most of the piles are of hollow cross-section, 22 in. external diameter, 13 in. internal diameter; the penetration was about 22 ft. To provide sufficient impermeability, the shells of the piles were made of 1:1½:3 concrete, the fill being of a weaker mixture. Apparently, no cross-bracing system was used, the outer end of the pier being stiffened laterally by inclined bracing piles at regular intervals.

Atlantic City.—At Atlantic City the famous steel pier was widened and protected in 1906 by the use of concrete. The original pier was founded on steel-pipe piles resting on cast-iron disks, a type of construction quite common during the last part of the 19th century. The pier extends out into the Atlantic Ocean a total length of 1 600 ft. In rebuilding the pier all the original metal work was encased in concrete and the pier was widened on both sides, 12-in. and 25-in. reinforced concrete piles, with enlarged footings, being used. The smaller piles were pre-moulded vertically, on a small platform, each pile at its final location. After hardening sufficiently they were lifted off their platforms and jetted into place through from 8 to 14 ft. of sand. The larger piles were given a penetration of 16 ft. The lower 12 ft. of these piles were pre-moulded on a platform, a water-tight iron casing was secured to the upper end, and the whole was jetted into place. The dry caisson was then filled with concrete up to the proper level, the maximum total length of the 25-in. piles being 52 ft. In protecting the original piles, concrete shells were cast around them, with sufficient interior clearance, and the space was afterward filled with grout.

After the concrete work of this structure had been in the sea water for 6 months, the piles became coated with a sort of gelatinous matter which seemed to act as a most excellent protective coating against any deterioration. The same peculiar action has also been noticed in California.

Although not exactly a dock, it is of interest to note the concrete pile Boardwalk at Atlantic City. Not only is it necessary to guard against dry and wet conditions at such resorts, but the fine sands act like a sand-blast when driven like snow before the wind. In 1908 part of the old wooden structure was rebuilt with 16-in. concrete piles, supporting a concrete cap, and that in turn carried the wooden decking.

Baltimore.—It is perhaps at Baltimore that the most extensive reinforced concrete docks on the Atlantic seaboard have been built. Although the water in Baltimore Harbor may not have the same density of salt as in ports nearer the sea, these docks, thus far, have shown no sign of deterioration, though at times subject to frost action. Three of these piers are of a back-filled concrete bulkhead type, and are not docks resting on piles. Pier No. 4 is 978 ft. long and 220 ft. wide; Pier No. 5 is 1 245 ft. long and 200 ft. wide at the shore end, but 243 ft. wide at the water end; Pier No. 6 is 1 456 ft. long and 93 ft. wide at the shore end, but 212 ft. wide at the water end; all were built in 1908.

In general, these three docks consist of a series of oval-shaped concrete cylinders 25 ft. apart along the face of the docks, and sunk to about 25 ft. below low water. Along the face of the cylinders, and just above high water, there is a concrete-encased iron girder, tied back to a deadman some 28 ft. in the rear of each cylinder. A row of concrete sheet-piling was driven back of the girders to form a vertical retaining wall, the upper ends of the sheet-piling bearing against the girder, and the lower ends being driven into the muddy bottom. A horizontal box-girder encased in concrete runs along the upper face of the dock, supporting the outer edge of the concrete curb slab, on which are laid the paving blocks. The cylinders are tied together in certain cases by ties extending entirely across the docks. The face of each dock is protected by wooden fender-piles, 8 ft. apart. Another concrete dock has been completed recently in Baltimore by the Harbor Commission, the details of which are lacking. In the

same harbor is found a concrete bulkhead dock, built for a private corporation—a reinforced concrete sheet-piling structure capped with a concrete girder tied back to deadmen by reinforced concrete ties.

At Sparrows Point, near Baltimore, a reinforced concrete ore dock, 600 ft. long, was built in 1911. It consists of two parallel concrete walls, about 46 ft. apart, *viz.*, (1) a sheet-pile bulkhead on the water-front capped by heavy concrete girders with a cantilevered shelf, as it were, on the outer face, running the full length of the bulkhead; (2) a heavy retaining wall in the rear, the two walls being tied together by reinforced concrete ties about 30 ft. apart. The back wall, resting on wooden piles, not only acts as a deadman for the outer wall, but affords a means for carrying one track of the large, heavy, ore unloading crane that straddles the filled-in space between the two walls, the front track of the crane running along the outer wall. The dock face is protected by a substantial system of fender-piles and wales with heavy helical car-springs at each buttress of the face wall.

Norfolk.—In constructing the Virginian Railway Coaling Terminal, at Sewells Point, in 1907, it was not practical to carry the massive steel superstructure on creosoted piles. In place thereof groups of wooden piles were driven and cut off 1 ft. below the mud line. On top of these piles were built monolithic concrete piers, of pyramidal shape, to 4 ft. above high water. All the concrete work was done in the dry, inside a coffer-dam. These piers are reported to be in as good condition as when first built.

Brunswick and Charleston.—Perhaps the most extensive development of concrete dock construction, combining concrete piles with wooden decking, is found at Brunswick, Ga., and at the U. S. Navy Yard, Charleston, S. C., built in 1906.

The Brunswick terminal consists of two piers, 500 and 900 ft. in length, respectively, and each is 140 ft. wide; there is also a coaling pier about 300 ft. long. The 16-in. bearing piles, of pre-moulded concrete, are 12 ft. from center to center each way. They are from 30 to 51 ft. in length, with the lower 10 ft. tapering to 8 in. The piles have a penetration of 40 ft. Their upper ends are corbeled out to support the double 8 by 16-in. wooden caps. The decking consists of 6 by 14-in. stringers and a 3-in. flooring. Each bent is well braced with creosoted wooden cross-bracing.

The Charleston Navy Yard dock is 60 ft. wide and 520 ft. long, and of the same type of construction as the Brunswick structures. The piles, 10 ft. from center to center each way, are 18 in. square, instead of 16 in. square, and have an 8-ft. taper to 12 in. square at their lower ends, thus giving a heavier structure than those at Brunswick. The test load on the Charleston dock was 30 tons per pile for 48 hours, though the specification required only 20 tons, or 400 lb. per sq. ft.

The outer row of piles in these docks consisted of three creosoted yellow pine sticks, two of which were driven on a batter; all were bolted together to afford sufficient protection to the dock in the form of a fender-pile system.

During the building of the Brunswick dock it was rammed by a large steamer. Although a number of the pine piles were broken, it has been stated that the concrete piles withstood the shock successfully.

Savannah.—A rather unique type of concrete dock was built at Savannah, 17 miles from the sea, in 1913. The design seems to contain many of the excellent features of the Ambursen dam. This dock consists of a series of pile bents athwart the dock supporting reinforced concrete brackets of triangular shape, the brackets in turn supporting a concrete deck-slab sloping down and toward the rear of the structure. This deck was afterward back-filled and finished off with a suitable working face. The dock forms a water-front structure, and is protected by wooden fender-piles.

Jacksonville.—In the construction of a semi-concrete dock at Jacksonville, the Braxten concrete pile was used, with very satisfactory results. In another case the Ripley concrete-encased wooden pile was adopted.

Key West.—A reinforced concrete quay wall dock, 1 589 ft. long, was completed at the U. S. Navy Yard at Key West in 1912. The main wall consists of a series of pre-moulded concrete pile bents capped by a concrete girder and a deck-slab 40 ft. wide on top. From the inner edge of the deck-slab a sloping concrete apron runs down to the top of a row of sheet-piles which forms a retaining wall for the reclaimed land. The piles are from 16½ to 20 in. square, and vary from 25 to 60 ft. in length. The bents are 10 ft. apart, with the same spacing for the piles, each bent having six piles. The face of the dock is protected by a system of creosoted fender-piles placed midway between each bent.

Port Arthur.—A reinforced concrete pile-bent dock, 1 050 ft. long and 25 ft. wide, was constructed at Port Arthur, Tex., in 1911-12. In general, the piles are 16 in. square, 44 ft. long, and 5½ ft. from center to center. The pile bents, of five piles each, are about 23 ft. apart, and are capped with a reinforced concrete girder. Five concrete beams, running from bent to bent, and a 4½-in. concrete slab, form the deck structure. The dock is tied back to the concrete trestle built for carrying the railroad tracks in the rear of the dock. No provision is made for any spring or other device to take up the impact forces on the fender system, as it is believed that the wooden fender-piles will afford sufficient elasticity to prevent any injury to the dock from this source.

Cuba.—Two reinforced concrete docks, 620 and 670 ft. in length, respectively, and 160 ft. wide, were built in 1911-12 at Havana, the depth of the water varying from 12 to 40 ft. Each consists of a concrete floor-slab resting directly on concrete caps placed on top of clusters of from four to eighteen reinforced concrete piles, the clusters being about 23 ft. from center to center in each direction. The concrete piles, 18 and 20 in. square, were designed for a load of 32 tons each. The design of the floor slab would indicate a cantilever effect longitudinally between each row of longitudinal piling.

One of the railroad companies of Cuba, also, has built a reinforced concrete dock at Havana, for coaling purposes. The structure, which is subjected to very heavy loading, rests on Chenoweth concrete piling, and was but recently finished.

Haiti.—In constructing a reinforced concrete dock at Port au Prince, during 1913, the Ripley type of concrete wrapped wooden pile was adopted. This dock has a total length of 2 326 ft., varying in width from 24 to 60 ft. The piles are 10 ft. from center to center, longitudinally and transversely, and are capped by heavy concrete girders of rectangular section for the inshore end of the dock, otherwise by arched girders. The deck system consists of a series of reinforced concrete beams supporting the concrete deck-slab, built with a crown, in order to shed water. The dock is protected by a creosoted fender-pile system.

Panama and Canal Zone.—The United Fruit Company in 1909 built a combined reinforced concrete and wooden pile dock at Bocas del Toro, for the docking of fairly large steamers. The wooden piling is surrounded by a 4-in. concrete shell up to about 1 ft. above the

high-water line. The piles are extended up to the deck as reinforced columns, with a concrete beam and deck-slab system. Up to the present time the dock is said to have given good results.

In the Canal Zone the U. S. Army Engineers have constructed a reinforced concrete dock, 706 ft. long and 55 ft. wide, for unloading timber. There are fifty-five concrete piers or columns, 8 ft. in diameter and about 80 ft. long arranged in two rows, 35 ft. from center to center across the dock, and 30 ft. from center to center longitudinally, and built in the form of hollow reinforced concrete sectional cylinders. After these cylinders had been sunk to bed-rock, they were filled with concrete, being reinforced vertically with eight rails. On top of the columns there is a concrete girder, deck-beam, slab system. The girders are about 5½ ft. deep, the beams about 4½ ft. deep, and the slab 6 in. thick. The railroad track runs over one row of columns. The floor system is designed for a load of 400 lb. per sq. ft., with a concentrated load of 105 tons over the track beams. The depth of water for a mean sea-level tide is 40 ft., the total fluctuation in the tide being 20 ft.

Two other concrete docks of extensive size are now in course of construction in the Canal Zone, with still more to follow.

Pacific Coast.

On the long stretch of our Pacific Coast, perhaps is found the greatest development of reinforced concrete dock construction in the United States. This section is making vast harbor improvements in anticipation of the opening of the Panama Canal.

San Diego.—At this most southern port on the California Coast an extensive reinforced concrete dock is now under construction. It consists of two parts, *viz.*, the dock itself, 800 ft. long and 130 ft. wide, and a quay wall or bulkhead, 2 675 ft. long and 25 ft. wide. Wooden piles are driven into the soil and cut off "at any point between mean low water and 18 ft. below city datum." Each of the 42-in. concrete columns encases one wooden pile and supports a system of structural deck-beams, a concrete slab covering the whole. The columns are 15 and 13 ft. 4 in. from center to center. The entire structure is protected by a wooden fender-pile system having the so-called San Francisco type of steel spring shock-absorbers.

San Pedro.—In connection with extensive port developments at San Pedro, a semi-reinforced concrete dock was recently completed in the outer harbor. It consists of pre-moulded concrete piles, 10 ft. from center to center in each bent, the bents being 16 ft. apart. The tops of these piles are corbeled out to support two 10 by 16-in. wooden caps, which in turn support the wooden floor joist and wooden decking. The piles are tied together with a wooden cross-bracing system above mean high tide. The structure is also stiffened against lateral blows on its face by inclined bracing piles. The wooden pile fender system has a car-spring to assist in taking up lateral forces. The dock is of the quay type, 48 ft. 6 in. in width, the total pier head frontage being 12 000 lin. ft. A railroad runs parallel to the inner edge on the inshore fill.

Redondo.—It is of interest to take note of the ocean pier at Redondo, Cal., though it is not a dock. It extends some 637 ft. out into the Pacific Ocean, and supports the intake pipe (for cooling purposes) of a power station. The pier consists of concrete pile bents, 20 ft. apart, each bent having four piles. As considerable surf runs at times under this pier, the outer bents have an extra outside pile driven with a batter of 2 in. per $\frac{?}{?}$ ft. The piles consist of a thin steel shell, 18 in. in diameter, closed at the lower end. After the steel cylinder had been driven to the proper depth of penetration, the reinforcement was inserted and the cylinder was filled with concrete. The piles of each bent have a structural steel cap encased in concrete, with a system of diagonal bracing in a horizontal plane connecting the tops; there is also a longitudinal system of ties at the tops of the piles, above the reach of the water. This structure, as a whole, is said to possess considerable elasticity.

Long Beach, Cal.—In 1907 a concrete pile pier was built at Long Beach, extending some 1 300 ft. out into the ocean. The head of the pier is 100 ft. long and 300 ft. wide, the approach being 1 299 ft. long and 32 ft. wide. The deck is 30 ft. above mean low water, so as to be kept clear of the 24-ft. waves which at times roll in from the ocean. The piles and columns are 4½ ft. in diameter, and are arranged in bents. Under the head of the pier the bents and piles are 16 ft. from center to center. The approach bents are 20 ft. apart, with two columns each. The columns are sunk from 10 to 18 ft. into the sand, in order to be absolutely safe, as it is said that at times the undertow

digs out the sand to a depth of 13 ft. The pile caps consist of steel I-beams, on top of which rest wooden stringers carrying a wooden decking.

Santa Monica.—At Santa Monica, an ocean pier, built in 1908-09, extends 1 600 ft. out into the ocean. It was built on driven concrete piling, ranging from 14 to 22 in. in diameter, in lengths up to 75 ft., with from 16 to 20 ft. penetration. Although the pier was built primarily to support the outfall sewer carrying the sewage effluent to a point far seaward, it is also used for recreation purposes. The pier is about 35 ft. wide at the deck line, with three platform spaces of 43 by 89 ft. at intermediate points and at the end. The bents are 20 ft. from center to center and consist of three piles, the piles being 13 ft. 6 in. from center to center. Each bent has a concrete cap on which rest the wooden joists covered with 2-in. planking, and the latter is covered with a 3-in. wire-mesh concrete slab, having the proper pitch to carry off the water. The bents are tied together by three longitudinal reinforced concrete tie-beams running from top of pile to top of pile. The piles are bulb-pointed.

San Francisco Bay.—Although the dock engineers of New York City have developed a type of semi-reinforced concrete dock, *viz.*, a wooden pile structure supporting a concrete slab, especially adaptable to local conditions, the dock engineers of San Francisco have developed a type of full reinforced concrete dock based on wooden sub-piling, concrete column piers, steel or concrete deck-beams, and concrete floor slab, the concrete encasing the steel beams and the floor being made monolithic, with details varying to suit special conditions. Although the type as worked out presents no difficulty in the way of construction, outside of building the main columns, that part of the work has been done successfully, but with considerable difficulty. The mud line at the bottom of the bay is said to be approximately level, yet, at the outer ends of some of the piers there is a depth of only about 18 in. of mud over the rock; at the shore end, however, there is a depth of 35 ft. of mud. Piles can be driven to a rock bearing in some places, but it is impossible to use wooden piles throughout. Along a portion of the water-front, where it is not possible to reach the rock, there is a hard soil capable of bearing from 4 to 6 tons per sq. ft., thus doing away with the necessity of any sub-piling.

The method used in building the column piers is to sink a hollow

steel caisson, of such length that it will not be overtopped by the water, dredge out the interior to the desired depth, and build the reinforced column in the dry. In some cases the columns rest on solid rock, in others, wooden piles have to be driven inside the cylinders to obtain the necessary bearing support. The size of the columns varies according to conditions. In two docks built in 1910, 140 ft. wide and 780 ft. long, where the mud covering the rock was less than 50 ft., the columns were seated directly on the rock. Where the mud is more than 50 ft. deep the columns rest on five 15-in. wooden piles driven to refusal, the piles being cut off 35 ft. below the water line and encased by the concrete columns to that height. The columns are 6 ft. in diameter to a height of 7 ft., and then 3½ ft. to the top.

In laying out a vast dock improvement proposition at Fort Mason, San Francisco, the Government has planned for the immediate construction of three docks of the usual San Francisco type, each to be 500 ft. long, two 81 ft. wide, the third 118 ft. wide. The concrete columns are to be supported by groups of seven wooden piles driven in a circle 6½ ft. in diameter, and 18½ ft. from center to center each way. The piers are to be 8 ft. in diameter up to 12 ft. above the dredge line, and are then to be reduced to a diameter of 4 ft. for the remainder of their length. The wooden piles will extend some 11 ft. up into the concrete columns, the bottom of the concrete being well below the mud line. In building the first of these docks, an attempt was made to construct the column forms of 4-in. staves, sufficiently reinforced with bands, and sink them into position by driving. The method did not prove a success, and resort was made to the steel cylinder caisson method, as described previously.

Up to 1911 there were only four modern reinforced concrete column docks under the control of the San Francisco port authorities. Since that time they have added largely to the number by replacing some of the older wooden pile docks with reinforced concrete structures. The first addition was Pier No. 17, 800 ft. long and 126 ft. wide, with suitable railroad track accommodations. It consists of wooden piles protected by concrete shells, the deck-beams being of structural steel encased in concrete, and the stringers and decking are of timber—a sort of semi-concrete pile semi-concrete dock.

The next docks reconstructed were Piers Nos. 26, 28, 30, and 32, all of the same type, having reinforced concrete columns resting on

the hard bottom, without any piling, with a complete system of reinforced concrete deck-beams, girders, and slabs. These docks are equipped with up-to-date cargo-handling machinery.

The next addition was Pier No. 39, 150 ft. wide, this being in process of construction at the present time. The concrete columns rest on groups of from 4 to 10 wooden piles, the entire deck system being of reinforced concrete.

In another type of construction at San Francisco the wooden piles are wrapped with wire fabric, or otherwise, and a concrete shell is placed around them after the piles have been driven to place. This method, apparently, has proved successful, though it must be carried on in such a way that the concrete can be poured, set, and hardened in the dry, and not in sea water, if permanent results are to be obtained.

Recently, the City of Oakland, Cal., built a genuine reinforced concrete pile dock, 295 ft. long and 124 ft. wide, standing in 30 ft. of water. The piles are of pre-moulded concrete, 16 in. in diameter, octagonal, and of a 1:1½:3 mixture for a distance of 5 ft. from the top, the remainder of the pile being of a 1:2:4 mixture. The bents and piles are approximately 10 ft. apart. Each row of piles has a concrete cap or girder running athwart the dock, the deck-beams and deck-slab being also of concrete. For lateral stiffness, 12-in. concrete curtain-walls were built at three points in the dock, for about one-third of its width, between the piles in three bents.

Portland.—Being 112 miles from the ocean, on a fresh-water river, it is possible to use wooden piling at Portland, in the construction of docks. A massive concrete dock terminal, now being built by the city, consists of four concrete warehouses along the water-front. The dock part of this project as designed consists of a reinforced concrete platform, 1 030 ft. long and 100 ft. wide, 32 ft. above low water, resting on wooden piles driven in groups and cut off at about mean low water. Resting on each group of wooden piles, 20 ft. from center to center, are the reinforced columns supporting the upper platform, composed of steel I-beams encased in concrete, and a concrete floor-slab. For a length of 300 ft., a low-level deck, 14 ft. below the main deck, is provided. As the Columbia River is subjected to high- and low-water stages, due to floods, it was necessary to provide this lower platform for use by river steamers during low-water periods. The rise

and fall of the Columbia River attains a maximum of about 28 ft., though 18 ft. is about the average, all based on mean low-water level. Thus the lower platform will seldom be under water.

Puget Sound.—Though there are several large shipping ports on Puget Sound, up to the present time, no reinforced concrete dock construction of a commercial nature has been undertaken in these waters. As lumber is so plentiful in that part of the country, it is only natural that such a section should be one of the last shipping centers to take up the building of reinforced concrete docks; but as the destructive teredo is very active there, the engineers of the Northwest are beginning to seek a more stable type of construction than creosoted wooden pile docks, especially the United States and Canadian Governments, and some of the railroads, because "in Government [and publicly owned] docks, a small saving in first cost is of minor importance, but weakness and frequent need of repairs are well nigh intolerable. On the other hand, in private ownership of docks a saving in first cost is usually of serious importance, while the cost of maintenance, repairs, etc., is met by earnings of the dock and is less felt", unless they become so excessive as to make a concrete proposition more economical in the long run.

At the U. S. Navy Yard in Bremerton, Wash., a reinforced concrete dock, consisting of concrete columns, steel and concrete beams, and a concrete slab, was completed in 1912. It is 402 ft. long and 60 ft. wide. The columns are 3 ft. in diameter, with a flared-out footing to a diameter of 6 ft., 16 ft. from center to center, each way, there being four columns to each bent. The caps and girders over the tops of the columns are of I-beams encased in concrete. A concrete beam is run midway longitudinally between each of the four steel beams. The I-beam caps are cantilevered out 6 ft. on each side of the dock. The columns were built as hollow concrete cylinders with a 3-in. shell of 1:2 mortar, and filled with a 1:2:4 concrete after being sunk to place. As hollow cylinders, they avoided any coffer-dam work. The dock has a standard railroad track down each side over the outside columns, also an ordinary wooden fender system.

A still heavier concrete dock is now in course of construction at the same Navy Yard. It is 490 ft. long, 80 ft. wide, and is designed for a load of 600 lb. per sq. ft. The approach of the dock consists of a wooden pile structure, 210 ft. long, of triangular shape. As designed, the structure is supported by sixty-eight concrete columns, 4 ft. in diameter,

with an 11-ft. base (of the same type as in the dock just mentioned), 20 ft. from center to center athwart the dock, and 30 ft. longitudinally. The columns are capped by extremely heavy reinforced concrete beams which support a series of built-up structural beams, about 36 in. deep, carrying a thick concrete floor-slab. The side of the dock is cantilevered out 8 ft. beyond the columns. A standard railroad track runs over the center line of the outside rows of columns on each side of the dock. On account of the nature of the soil, some of the piers rest on sub-piling, others, nearer the shore, on hardpan.*

Vancouver.—The Great Northern Railroad has very recently completed an extensive reinforced concrete dock of the quay type, in connection with a new terminal it is building at Vancouver. The total width of the terminal dock is 302 ft., the concrete dock proper being 456 ft. long, and 50 ft. wide on each side of the terminal, the space between being a rock and earth fill, with a proper rip-rapped slope at its faces. Each concrete dock structure consists of nineteen reinforced concrete columns, 4½ ft. in diameter, 25 ft. from center to center, parallel to the face of the dock, resting on the rock stratum that underlies the location of the terminal. These columns support a heavy longitudinal concrete girder into which are tied heavy cross-girders, 12½ ft. apart. The cross-girders are cantilevered out beyond the longitudinal girder about 16½ ft., and their inboard ends rest on two driven concrete piles 34 ft. back from the center of the columns. Four concrete beams of suitable size are run longitudinally with the dock. The entire girder and beam structure supports a concrete slab. The railroad track is over the longitudinal girder running from column to column. The two parts of the dock are tied together by suitable concrete beams running across the interior fill. The terminal is considered to be one of the most substantial and up-to-date structures on the Pacific Coast. The dock is well protected by a wooden fender-pile steel-spring system.

Great Lakes.

Although extensive use of concrete has been made in some of the ports of Lakes Superior, Michigan, Huron, Erie, and Ontario, in the construction of massive ore-docks, it is not proposed to discuss that particular phase of the subject in this paper. These docks are of

*In the actual construction the built-up structural beams were replaced by reinforced concrete.

excellent design, some built on concrete piling, others on wooden piling or cribs. Concrete piles in fresh water are not subjected to the same deterioration as those in salt water. On the other hand, they have to withstand extremes of temperature, frost and ice, in addition to severe treatment, due to the heavy traveling machinery above them.

Some of these docks will be discussed, in order to bring out the important features of their special design.

Chicago.—One of the first attempts at using concrete for dock work on the Great Lakes was made at South Chicago, in the winter of 1898-99, in the rebuilding of an old wooden quay dock wall. The concrete structure is 1 680 ft. long, and consists of a heavy mass concrete stepped-back wall, 10½ ft. high, 8 ft. wide on top, and 18 ft. on the bottom, supported by a timber structure consisting of three rows of piling cut off 3½ ft. below mean water level, with longitudinal caps crossed by a heavy wooden grillage. A timber sheet-piling bulkhead under the face of the wall acts as a retainer for the slag fill. On one occasion the wall was rammed by a large steamer, but suffered absolutely no damage. The damage to the steamer, however, was rather extensive. A year or so later, a similar quay dock wall, 2 300 ft. long, was constructed at the same steel plant.

Due to the decay of a long wooden water-front bulkhead on the Chicago River, it became necessary to replace it. This was done by constructing a reinforced sheet-pile bulkhead almost ½ mile in length, capped by an I-shaped concrete beam, some 3 ft. wide and 5 ft. high. This beam rests on pre-moulded piles, which are 20 ft. apart and are secured to buttresses, also 20 ft. apart, which run back about 12 ft. from the sheet-piling, the land ends of the buttresses being supported by other piles. The buttresses are also tied back to deadmen some 35 ft. back from the wall. As the bulkhead has about 18 ft. of water along its front, vessels can dock alongside.

Marquette.—The most extensive reinforced concrete ore-loading docks on the Great Lakes are without doubt at Marquette, Mich., and were built in 1912. The substructure consists of a heavy concrete slab and facing-walls, similar to a channel beam placed on its back, 1 500 ft. long and 60 ft. wide, resting on wooden piling. Under the face of the walls there is a wooden sheet-piling bulkhead which retains the sand fill around the piles under the dock structure. The depth of

the concrete web is 3 ft., the walls that correspond to the flanges being 9 ft. high. The substructure supports a very massive reinforced concrete superstructure for loading ore into vessels, the whole dock being a very substantial and shock-resisting structure. A steel plate is worked along the face of the two concrete walls from 6 in. below the water level to 3 ft. above it, to prevent disintegration of the concrete due to frost and ice action at the water level.

Two Harbors.—At Two Harbors there is an ore-loading dock consisting of a steel superstructure supported by a mass concrete wall running along each face of the dock, and tied together with concrete beams at regular intervals. The concrete walls rest on wooden piles with a wooden sheet-piling bulkhead to retain the interior fill. The substructure is 1 400 ft. long and 52 ft. wide.

Detroit.—The concrete ore-loading dock at Detroit is 200 ft. long. It consists of three bearing walls of a T-rail shape, 9 ft. deep, running parallel to each other, the two outer walls being 28 ft. apart, the third or back wall being 173 ft. from the middle wall. The three walls rest on a double row of oak piling cut off 3 in. above the water level. Being capped by the concrete walls, no part of the wooden piling is exposed to the air. The outer wall stands in about 10 ft. of water, the middle wall in 3 ft., and the rear wall is far back on the dry land. The two outer walls are tied together by reinforced concrete beams, 5 ft. deep, at intervals of 10 ft., with cantilevered brackets on the water face of the outer wall opposite the tie-beams. The concrete deck-slab on top of the brackets is 12 in. thick, but only 6 in. thick between the two outer walls. The dock has a suitable wooden fender-pile system.

Between the middle and back walls there is a 12-in. reinforced concrete floor-slab, supported on a series of piles, 5 ft. from center to center each way, stated to have been designed for a load of 6 800 lb. per sq. ft., or 85 tons per pile. The ore floor is tied into the middle and back bearing walls opposite each cross-beam in the dock proper. The three walls support an ore bridge tower, used for unloading ore from vessels to cars on the track just behind the middle wall, or into the ore bin between the middle and back walls.

Toledo.—At Toledo, Ohio, there is an ore-unloading dock, consisting of a plain concrete wall running along the water-front, resting on wooden piles, and tied back to deadmen some 100 ft. in the rear. The

land is reclaimed back of the middle wall, a row of sheet-piling under the river wall retaining the earth in place. Parallel to the river there are three other walls to support the legs of the ore-unloading bridges which run on tracks placed on all four walls, spanning the four car tracks and the ore piles. The distance from the front wall to the inmost land wall is 419 ft.

Cleveland.—There is a full reinforced concrete ore-unloading dock at Cleveland, Ohio, completed in 1912 by the Pennsylvania Railroad. It consists of a reinforced concrete water-front wall, 985 ft. long, supported by a double row of pre-moulded concrete piles. The face wall is tied back by reinforced concrete tie-beams to another reinforced concrete wall supported by three rows of concrete piles about 81½ ft. in the rear. The tie-beams are 30 ft. apart, and rest on concrete piles 6 ft. apart. The space between the two walls, that is, under the concrete tie-beams, is back-filled with rip-rap, the whole mass being pumped full of sand. A concrete sheet-piling bulkhead under the front wall retains the fill in place. The dock has the usual wooden fender-pile protection. The tracks for four 17-ton Hewitt unloading machines run along the inner and outer walls. So far as the writer has been able to discover, this was the first concrete pile dock built on the Great Lakes.

Another ore-unloading dock at Cleveland consists of a reinforced wall of the same type as that at Detroit, the two structures having been designed by the same engineers. The cantilevered face of this wall is supported by brackets at intervals of 15 ft., with rear buttresses opposite them. The buttresses rest on a concrete base slab, the rear edge of which rests on a row of wooden sheet-piling, the base slab evidently being monolithic with the rest of the wall. The space between the sheet-piling and the wooden piles that support the concrete wall (11 ft.) is filled with slag. In general, the cross-section of the wall is dumb-bell shaped.

General.—In discussing the ore docks of the Great Lakes, it is necessary to consider the special and peculiar conditions under which they are operated, as they are designed to meet these conditions, and not *vice versa*. The larger portion of the freight carried on the Great Lakes is of heavy bulk form, *viz.*, ore and grain on the downward trip, coal on the upward trip. Thus ore and coal cargoes form the two heaviest items handled in bulk masses at the terminals. Nowhere in

the world is found such massive and modern machinery for the economical and expeditious handling of bulk freight as at the upper and lower ports of the Great Lakes. Consequently, such docks, wooden or otherwise, must not be judged by the type used along the seaboard of the Atlantic, the Gulf, or the Pacific.

It appears that the various types of reinforced concrete docks as worked out by the American engineers are far more numerous than in foreign practise, as is evident from the foregoing descriptions. Although the Atlantic Coast engineers seem to favor premoulded concrete piles, the Pacific Coast engineers apparently favor large concrete columns. Perhaps in time a typical American concrete dock will be designed or devised, as in the case of the long-standing type of wooden pile dock structures.

In the foregoing review of American reinforced concrete docks, an effort has been made to include each and every port wherein such types of docks exist, as well as to mention each and every dock already built, so far as the writer has been able to acquire sufficient information concerning them, in order that the exact situation as regards the development of reinforced concrete dock construction in America up to the present time may be known to all. If the writer has unintentionally omitted any such dock structure, he will be pleased to receive information relating to it.

The writer has endeavored to determine which was the first complete reinforced concrete dock constructed in the United States, but has been unable to do so. The concrete dock wall built at Chicago in 1898-99 appears to have been the first of its kind constructed on the Great Lakes. A study of the constructive dates of concrete pile or concrete column docks would indicate that such types began about 1905 or 1906. Still, it is not evident which was the first of such docks to come into existence, the whole development being a gradual evolution from a concrete-filled steel cylinder column, steel deck-beams, and concrete-slab type, as used in the Philippines by the United States Government in 1902.

Irrespective of the actual beginning of constructing reinforced concrete docks, it is generally conceded that Oscar F. Lackey, M. Am. Soc. C. E., Harbor Engineer of Baltimore, was among the first, if not the first, to blaze the way for the extensive use of reinforced concrete in dock construction in United States harbors.

PART III.—FAILURES OF REINFORCED CONCRETE STRUCTURES SUBJECTED TO SALT WATER ACTION.

In discussing reinforced concrete docks, the fact that there have been failures among them must not be overlooked. In Massachusetts waters, north of Cape Cod, a number of serious cases of deterioration of concrete have been caused by the disintegrating effects of sea water, wave action, and frost, especially in Boston Harbor, where nearly all the concrete structures standing in sea water have been affected badly between high and low tide, the most notable instance of which is the concrete pier at the Charleston Navy Yard. Although that part of the pier which is constantly submerged has given but little trouble, the part exposed alternately to the sea and air has been seriously affected, many large pieces having broken completely away, making it self-evident that some other agent than the chemical action between cement and sea water was at work.

As is well known, winter temperatures on the whole eastern front of the New England Coast run far below zero. In Boston Harbor 12° below zero is not uncommon. In the same way that hard earth and porous rocks are broken up by frost action, permeable concrete in freezing water will gradually be destroyed between wind and sea, as the water which gets into the concrete simply exercises its natural expanding function in freezing, which *a priori* is detrimental to the concrete structure. It is generally admitted that the exterior concrete in these Boston structures, especially in the Navy Yard pier, has failed almost entirely from the effect of the alternate freezing and thawing with each tide during the winter, due to permeable concrete.

A number of failures similar to that already cited have occurred in Boston, the disintegration taking place in all cases between low and high tides. In the case of the Dover Street draw-bridge pier, built in 1894, the disintegration had extended 1.4 ft. into the pier at the end of 17 years, the greatest damage being just below high-tide level. The pier was built of 1:2:5 concrete, with a 1-in. plastered mortar facing. English Portland cement was used throughout. Whether the 1-in. facing mortar was expected to act as a water-proof shield to the interior concrete is not apparent. Evidently, it did not act thus, as might have been expected.

As all the concrete in these disastrous cases seems to have been placed in the wet, that is, the sea water was allowed to come in con-

tact with the concrete before it had become thoroughly cured and hardened, such results are not to be wondered at, for one of the axioms of a successful use of concrete in sea water is that it must be kept from contact with sea water for such a period of time as to enable it to become thoroughly hardened, especially that part between tides in freezing climates.

In several cases in Boston Harbor where the concrete was placed inside of a coffer-dam, or used in the form of pre-moulded, driven, concrete piles, the concrete does not seem to have been affected as in the other cases cited. These successful cases go a long way toward substantiating the truism that concrete, to be used successfully in sea water, especially in freezing water, must be made impermeable in the process of making, with full consideration given to the brand of cement used, the mixture, the sand, and stone (or gravel), the skilled labor of placing, as well as keeping it from contact with sea water until it has set and hardened sufficiently. It is very apparent, from a study of the method used in placing the concrete in the disintegrated structures in Boston Harbor, that that method was far from possessing the essential features necessary for a successful solution of the problem, viewed in the light of present-day knowledge.

In comparison with these Boston failures, it is fitting to state that at Dundee, Scotland, where the climatic conditions are said to be worse than at Boston, and where there is a rise and fall of the tide of about 12 ft., the combined action of the sea, waves, and frost has had no ill effect on the concrete docks in that harbor, the concrete piles of which were allowed to harden for 30 days before being put in place.

Another noted case of the destruction of concrete by frost and sea action is the large concrete sea wall along the water front of Lynn, Mass.—a massive concrete sea wall exposed to the pounding of the winter storms and seas. The steps to the beach in the front of this wall were destroyed to such an extent as to be hardly recognizable as steps. It might be of interest to state that this wall and some of the damaged structures in Boston harbor have apparently been repaired effectively by the cement gun process.

In reviewing these failures in Boston and vicinity, it is well to consider the results obtained in using concrete in another port subject to freezing and ice conditions, *viz.*, New York Harbor. In addition to freezing conditions, New York Harbor has to contend with a

strong tidal effect, which results in large solid ice floes and fields of broken ice moving back and forth with a tide of considerable velocity, ice floes of such size coming down the Hudson as at times practically to compel abandonment of all transfer traffic in that river. This is an effect from which Boston docks are perhaps free, as no large rivers flow into that harbor, the Charles being kept under control by the so-called Charles River Dam.

In discussing this additional handicap and destructive force at work on New York City's 8¼ miles of concrete sea walls, some of which have been in existence for 41 years, Charles W. Staniford, M. Am. Soc. C. E., Chief Engineer of the New York Department of Docks and Ferries, states:

"Up to the present time [August, 1911], no disintegration has been discovered that can be attributed to the existence of the structure in salt water. The concrete itself is in an admirable state of preservation, absolutely hard, and is undergoing no regular process of disintegration." * * * "this sea-wall which has been under construction * * * for 41 years, is at the present time an excellent piece of work and is subject to the same climatic conditions as all cities on the Northern Atlantic Coast with the attending ice, cold and rain characteristic of this latitude."

In many instances, parts of this wall above low water are faced with granite blocks. This is a noted example of what can be expected in the way of using mass concrete in sea water if properly made, though perhaps some repair work has been necessary in order to maintain the excellent condition of the wall.

In some of the earlier sections of this wall the concrete was placed *"en-mass*-in-site", but, since 1876, most of the wall has been built by the concrete block method. Only under specially favorable conditions is it possible to place concrete successfully *in situ* under (sea) water, as it becomes disintegrated "through the chemical action of the sulphate of magnesia on fresh concrete or through the resulting porosity of concrete due to the impossibility of tamping under water",* the viscosity and weight of the mass not being sufficient to produce such a dense material as obtained in block work.

To discuss an opposite case in New York Harbor, *viz.*, Dry Dock No. 2, New York Navy Yard, originally built of timber in 1890, the

*This subject is discussed further by the writer in an article entitled "Chemistry of Salt Water Cement," *Metallurgical and Chemical Engineering*, January and February, 1914.

history of which it is not necessary to relate here: In 1900 this dock was rebuilt, concrete being used very extensively. During 1913 a large sum was expended in repairing and replacing the concrete altars and floors. As it has been stated that the difficulties of using concrete in sea water have been so great at this yard as to indicate that this is not a permanent material for use in sea water structures, it would be of deep interest to learn the facts as to the chemical composition of the cement used, of the sand and stone, as to the mixture thereof, and the precautions taken in mixing and placing; also as to whether the dock is kept flooded when not in use, especially during the winter. If, as has been stated, the concrete "has deteriorated and disintegrated to such an extent that it was possible to use a pick and shovel in removing it", it is apparent that it was lacking in one or more of the essential features that are deemed absolutely necessary for a successful use of concrete in sea water structures.

Whether any of the concrete pile docks on the Great Lakes have shown any signs of deterioration due to frost action, the writer does not know, but trusts that some facts covering this question will be brought out in the discussion. As the water level is practically the same all through the winter, only a very short length of the pile would be affected, and not some 10 ft., as in Boston Harbor.

One of the first concrete docks built in San Francisco is said to have failed in part due to poor construction. The early method of building the concrete columns of San Francisco concrete docks was to use a wooden cylinder, strongly built, as a column form, into which, it has been stated, the concrete was poured, apparently without any attempt to pump out the cylinder. As long as the wooden cylindrical forms remained in place around the supposedly concrete column, the dock was pronounced a success. When the teredo had finally destroyed the forms, the columns began to collapse and the dock became a pronounced failure, because, in pouring the concrete, the heavier material —the stone or gravel—settled first, then the sand, and finally the cement. The result was that throughout the length of the concrete columns there were alternate layers of uncemented stone and sand, with the cement in between the sand of one batch and the stone of the following one. Concrete can be and is successfully dropped through a height of 50 ft.—and even up to 100 ft. in one noted case

in Arizona—but, if the receptacle into which it is dropped is full of water, disaster alone awaits the unfortunate engineer.

In another of the San Francisco docks, where wooden piles supported the concrete columns, the concrete was not carried down below the mud line a sufficient distance to prevent the teredo from destroying the piles below the concrete.

The question has been raised: Has any deterioration taken place in concrete structures standing in sea water in the harbors of the Southern States, where frost action is unknown. The most prominent concrete structure thus situated is the famous viaduct across the Florida Keys, built of Alsen cement, imported from Germany. It is possible that some of the members of this Society are in a position to give complete information regarding the action of salt water and the waves of the Gulf on this structure.

In order to guard against the disintegration (irrespective of its cause) of mass concrete placed *in situ* above low water, or to repair any damage that has been done, besides the cement gun process, various methods have been used, all based on the fundamental principle of using an impermeable material for the facing of the structure. Below low water, properly made block work has given most satisfactory results. Carefully made, fully cured pre-moulded concrete piles seem to resist the action of the sea and frost successfully. In Holland, hard, impermeable brick have been used to prevent any further damage to one of the breakwaters above low water. In England, the upper parts of massive breakwaters are mostly faced with granite or some other hard suitable stone. In Nova Scotia, both brick and pre-moulded blocks of concrete of small size were placed on the face of a concrete sea wall after the disintegrated concrete had been removed. A still more recent device is the use of hollow, vitrified, salt-glazed tile blocks filled with concrete after being put in place. Experiments thus far seem to have proved that:

"Vitrified salt-glazed tile is impervious to any deteriorating action of sea water, and has an effective structure against the battering of ice; it is so dense as to preclude the possibility of any water entering and freezing in it to the consequent destruction of the tile."

Though oiled concrete is being used as a water-proof material in certain cases, it is possible that the refuse, oil, gases, etc., discharged from certain classes of buildings, etc., might have a destructive effect

on the concrete foundation piles or other parts of the building, especially in sea water heavily charged with sewage. It is a well-known fact that concrete sewers will not perform their duty properly for any length of time unless they have a brick lining invert, over which flows the heavy sludge. In time of flood the surface water is so great as to dilute the sewage and prevent injurious effects. The writer would be pleased to hear opinions on this point, as it is possible that a destructive effect might have been caused by sewage in connection with one of the most seriously affected cases in Boston.

Although poor results seem to have attended quite a number of the reinforced concrete structures standing in sea water in America, the opposite appears to have been true in foreign countries. Still, a few failures are on record as having occurred in England and Germany, due mostly to permeable concrete.

Part IV.—Construction and Maintenance Cost of Reinforced Concrete Docks.

Cost of Construction.—To attempt any discussion of costs is always attended with danger to the one who does so, especially when such figures are "published cost". To lay the foundations for a discussion of this side of the question, the data in Table 2 have been collected from various publications, their real worth depending on the reliability of the published figures. The data cover some of the docks mentioned in Parts I and II.

The first cost of the various reinforced concrete dock structures at Port Talbot is stated to have been "no more than if they had been built of wood." Such a statement would not perhaps be true in the United States, on account of the large forests in this country.

Maintenance Cost.—A few figures covering the cost of maintenance of reinforced concrete docks in England are noted. In addition to what has already been said on the maintenance question, the cold storage wharf at Southampton is reported to have cost nothing to date for maintenance. On the other hand, the widened dock and the coal jetties are said to have shown considerable deterioration due to rusting of the steel, it having been improperly placed in these structures. It has been stated authoritatively that "while six to seven years is perhaps a rather short time in which to form any definite conclusions, the maintenance cost [of the above described Port Talbot docks] has been practically nothing."

The annual repair charges on the Purfleet coaling jetty (exclusive of the damage done at the time of the collision) for the first 9 years of its existence are stated to have been but $50 per annum, which, based on its cost, $60 000, is less than one-tenth of 1 per cent.

TABLE 2.—COST OF CONCRETE DOCKS.

Location.	Type.	Cost per square foot.
Pier No. 8, Puget Sound Navy Yard...	Concrete columns. Steel deck-beams. Concrete deck-slab.	$3.11
Naval Station, Philippines.....	Concrete columns. Steel deck-beams. Concrete deck-slab.	2.60
Balboa, Panama Canal.....	Concrete columns. Concrete beams. Concrete deck-slab.	3.28
Oakland, Cal.....	Concrete piles. Concrete beams. Concrete deck-slab.	3.27
Brunswick, Ga.....	Concrete piles. Wooden deck system.	1.40
Charleston Navy Yard, S. C.....	Concrete piles. Wooden decking.	2.60
United Fruit Company, Panama.....	Concrete-protected wooden piles. Concrete deck-beams. Concrete slab.	2.13
Brooklyn, average of two docks.....	Wooden piles. Wooden caps. Concrete deck-slab.	0.90

Table 3, from data published by the Chief Engineer of the Mersey Dock and Harbor Board in 1910, gives some very interesting results as respects the cost of annual repairs to six of the reinforced concrete docks at Southampton.

TABLE 3.—ANNUAL REPAIRS, SOUTHAMPTON DOCKS.

Dock.	Erected.	Cost.	Cost of repairs to date.	Average per year.	Annual percentage, based on original cost.	Remarks.
A	1899–1900	$24 000	$800	$80	0.0033	Deck for Cattle Wharf, Prince's Jetty (wood piles).
B	1904–06	63 500	375	75	0.0012	Floor or deck on Hennebique piles, Prince's Dock, West Quay.
C	1900	13 800	80	8	0.0005	Floor for wharf, Coburg Quay.
D	1901	3 700	25	3	0.0008	Floor for wharf, etc., Brunswick Half Tide Dock.
E	1908	17 500	.....	....	.....	Floor for wharf, etc., North Quay, Brocklebank Dock.
F	1908	163 500	.....	....	.....	Treble-story shed, South Quay, Sandon Dock.

Dock *A*. Subject to the effect of moist air arising from water below it.

Dock *B*. Subject to effect of moist air. Piles more or less submerged, according to water level.

Dock *C*. Complete reinforced shed and pile foundation: not sufficient time to form any conclusion.

If the results in Table 3 are true, it is no wonder that the English engineers report that their reinforced concrete docks cost nothing for annual repairs.

Part V.—General Considerations.

Opinions of Foreign Experts.—Although failures have accompanied the use of concrete in sea water and in the construction of reinforced concrete docks, it must be admitted that, if the Engineering Profession did not meet with a failure now and then, it would never acquire anything new, as it is through failures that it gains the most vital knowledge of engineering.

(*a*).—In discussing the question of concrete docks, a prominent New York engineer has stated that, of the large number of concrete docks which have come under his observation, the majority have been a success, though here and there he reports a failure due to poor construction and material, and not to defects in the design. It is authentically stated that the reinforced concrete docks at Southampton have shown no deterioration due to salt water action, except at the Southampton coal jetty. The engineers of the Liverpool Docks have been using concrete in connection with their work since 1872, apparently with great success. It has been stated on the best authority that in England the alternation of "dryness and wetness and fluctuations in temperature" does not appear to have affected reinforced concrete sea water structures adversely.

Mr. Henry Hunter, Chief Engineer of the Manchester Canal, England, states that "the concrete in the concrete lock built at Eastham is in better condition at the present date than the day it was deposited", and adds that, covering an experience of more than 30 years of placing concrete in salt water, he has known no failures in such work where the concrete has been properly mixed and deposited.

In discussing the concrete docks of the Port Talbot Dock Company, Mr. William Cleaver has stated that:

"While reinforced concrete requires extreme care, both in the choice of material and in the supervision of the workmanship, the results justify the extensive adoption of the material for dock work."

The exceptionally experienced dock engineer, Mr. Francis E. Wentworth-Shields, of the London and Southwestern Railway Company, has stated that "if great care is exercised in making and placing concrete,

an impermeable material will be obtained which can withstand the action of salt water." Mr. Shields has also said, "while many engineers were nervous about the life of reinforced concrete (for sea structures), he had observed that maintenance engineers were not so nervous as construction engineers." He is inclined to feel that there is nothing special to be feared respecting the life of reinforced concrete when used in marine work. Although, under certain circumstances, it is likely to deteriorate, he does not think it will do so from simply standing in sea water. He says that though in some cases deterioration has taken place at Southampton above low water, it has not done so below low water; that a 10-year-old reinforced concrete structure standing in sea water at Southampton is in perfect condition at the present date; and that, during the whole experience at Southampton, sea water does not seem to have produced any chemical or other deleterious action on the concrete.

Experiments by Mr. Baldwin-Weisman, in 1907, in England, on the permeability of concrete, show that, if it is well made, it is one of the most water-tight materials known, and that it rapidly becomes less and less porous when water is forced through it.

Mr. V. De Blocq von Keuffeler, in summing up the experience in using concrete for salt water structures in Holland, says:

"A suitable mixture, very carefully manufactured, the use of a good brand of cement with trass, and setting in a moist atmosphere, are the most efficient means of ensuring the preservation of reinforced concrete in sea water."

Mr. I. Ho, one of Japan's expert harbor engineers, who used more than 1 200 mass-concrete blocks in one instance, none of which during a period of 10 years has shown the slightest signs of failure, states, "that whereas a good and proper cement is of consideration, the most important factor is the mode of fabrication."

In reviewing the successful experiences of some of England's leading authorities, the question of the chemical composition of the cement used does not appear to be given. Such information would be of great value, in order that engineers may know whether they use a cement especially manufactured for sea water concrete or simply the ordinary Portland cement, with or without puzzolana, trass, etc.

(*b*).—In discussing the deterioration of steel in reinforced concrete, by the action of sea water on ferro-concrete, provided the latter is properly made, Mr. C. S. Meiks, a prominent concrete engineer of England, says that such deterioration "is a negligible quantity." In

support of this contention he cites the experience at Southampton, stating "that the exposed steelwork on a pile end that had been in the sea for 8 years was much corroded", whereas the bars in the body of the concrete, on being cut open, were found to be quite free from any rust and as fresh as the day they were put into the pile.

In connection with the building of some of the earlier concrete dock structures at Southampton, it appears that parts or the whole of piles not used were allowed to remain on the beach or shore, exposed to sea water, for some 7 years. At the end of this period the exposed steel had been badly rusted and deteriorated, whereas the part which was embedded in concrete was found to be in fine condition, practically as good as the day it was placed in the concrete. Still, concrete piles lying on the beach are not in the same position as concrete piles subjected to shocks in a dock.

Though the first jetties, built 11 years ago in Southampton water, are in excellent condition at present, the steel in another jetty at the same location has deteriorated, due to electrolytic action.

It is generally accepted by all English authorities that no deterioration takes place in steel when well embedded in the concrete.

(*c*).—In speaking of reinforced concrete when used in marine work, Mr. Wentworth-Shields says "it will stand a wonderful amount of shock, and bending due to shocks, if a wooden fender is interposed." At a more recent date, Mr. Shields remarked: "On the other hand, reinforced concrete would not bear being knocked about by heavy ships, and where a structure was subjected to severe blows of that sort it was not easy to find anything better than timber, * * * but, when used at the right time and in the right place, reinforced concrete was a valuable material to dock engineers." From the leading position Mr. Shields occupies among the dock engineers of England, it would be of interest to know just what distinction there is between "a wonderful amount of shock" and "subjected to severe blows."

As an axiom: whatever system or design is adopted for a reinforced concrete dock, in no manner whatsoever should a vessel be allowed to rub against the main piling of the dock. The dock should always be protected by a system of fender-piles.

(*d*).—As respects the resistance of a concrete pier or dock, when under such treatment as the Purfleet pier was at the time it was rammed, in 1904, Mr. Meiks, engineer in charge of its construction,

states that "the vibration was so great at the time of the collision that they thought the entire pier would collapse, but that its elasticity was most satisfactory, due no doubt to its horizontal concrete decking." Mr. Meiks also says that the vibration of a concrete pier supported on piles is nearly as great as in a pier made of timber piling; but this has no particular effect on the structure, judging by the experience gained with the Purfleet pier at the time it was rammed.

In speaking of the Port Talbot docks, Mr. A. E. Carey has stated:

"If the structure [reinforced concrete dock] was properly designed and built, its stability and life were assured, the only serious drawback being the difficulty of repairing damage due to collision."

But how often do collisions happen?

The Chief Engineer of the Port of London, Mr. Bryson Cunningham, recently stated that the art of building reinforced concrete docks in England has attained a degree of perfection greatly in advance of early experimental work. If their early experimental docks are still doing good service, will not their more recent docks become structures of an engineering and commercial success, thus justifying the American engineer in recommending concrete docks as long as they are built in a manner to guarantee impermeability and non-deterioration of the concrete?

Concrete Breakwaters.—As the application of reinforced concrete to dock construction has been developed almost entirely since 1900, some of the most conservative engineers may not feel that sufficient time has elapsed to judge correctly as to the merits of using cement and placing concrete structures in sea water, and as to the advisability of adopting reinforced concrete as a coming type of dock structure. As respects the first point, the prolonged and successful use of mass concrete by foreign countries in breakwater, tidal, and graving dock work would in itself appear to be sufficient answer to all such skepticism.

Though an extensive treatise might be written on concrete breakwaters and their construction, including shore protection, those phases of the use of concrete in sea water are supplementary to the principal subject of this paper. There is apparently hardly a leading seaport or a maritime nation outside of the United States that has not made a wide, extensive and successful use of mass and reinforced concrete in the development of harbor and shipping facilities.

Surprising as it may seem, a number of large concrete breakwaters

have been in existence in Japan for more than 18 years. As a matter of fact, the use of concrete in the harbor work of Japan is far in advance of American practice, being apparently on the same high level as in England and other European countries.

Mass concrete has been used very extensively in Belgium and Holland for sea water structures for years, and has given the best of results. In fact, some of the concrete sea walls in the latter country, built in 1867-77 and earlier, are so old as to be called ancient, and have as yet shown no signs of being affected by the action of sea water. Perhaps such a statement needs to be qualified, because some of the principal harbors of Holland are some distance from the sea, and are in fresh or brackish water.

Concrete was used by the Romans and Carthagenians in ancient times. Though it fell into disuse for many centuries, it came into use again in 1840-50. To this day, sea walls built of puzzolana and lime cement by the Romans are in existence in Italy.

The Italian engineers report that Portland cement concrete with an addition of one-eighth to one-tenth by volume of puzzolana gave no signs of disintegrating in salt water, even after an exposure of 30 years in the harbors of Genoa, Civita Vecchia, Naples, etc.

At several places on the Italian coast concrete-faced breakwaters have been in existence since 1880, in most exposed positions, costing but little for repairs and maintenance, though subject to the high seas and heavy blows of the Mediterranean.

English engineers were using mass concrete in their tide locks and in the construction of massive breakwaters along the coast of England as far back as 1871, if not earlier. The fact that they have continued to use it more extensively each year, even to building vast reinforced concrete structures standing in sea water during the past 15 years, would appear, in spite of some failures, to be sufficient answer to any doubts the American engineer may entertain on the subject.

At Colombo, India, a concrete breakwater, finished in 1885, showed no failures above or below water at the end of 22 years. As stated above, some of the massive concrete breakwaters of the world have a hard stone facing, or are built of concrete blocks, with or without a stone facing.

The reasons that enable the foreign engineers to accomplish such lasting results with concrete is no doubt due to the fact that they, to-

gether with the foreign chemists and cement manufacturers, long ago learned the secret and acquired the art of manufacturing and using concrete in sea water structures. Though the American engineer excels the foreign engineer in certain lines of his profession, it must be admitted that, so far as using cement, and hence concrete, in sea water structures, the engineers of the leading European countries and of certain parts of South America are many years in advance. The American cement manufacturer, the chemist, and the harbor development engineer cannot long remain in such a position without reflecting on their ability as experts in their respective lines of work in the minds of their foreign contemporaries.

PART VI.—CONCLUSION.

In view of the marked success obtained by foreign engineers in the use of concrete for sea water structures, when the execution of such undertakings has been placed in the hands of intelligent, skilful, and experienced men, the American engineer who denies the possibility of making a successful use of concrete for structures standing in sea water puts himself in a questionable position. He thereby confesses either his lack of a world-wide knowledge on the subject, or his inability to carry out properly such classes of construction work to the same successful conclusions as his foreign contemporaries have been doing for years past. Such a confession would seem to indicate a lack of foresight and ultra-conservatism as respects the use of cement subject to sea water conditions, on the part of the American cement manufacturer, chemist, and concrete engineer.

The American engineer who assumes a skeptical attitude toward the practicability and commercial success of reinforced concrete docks has standing before him as silent testimony of their worth and practicability such a vast number of foreign reinforced concrete docks—several about 20 years old and yet in excellent condition, with still more massive structures being built each year, some of them costing less than wooden docks, if reports are true, and most of them saving their owners large sums annually on account of their low cost of maintenance and repairs, with no rebuilding, as with our 15-year creosoted wooden pile docks—that the grounds on which he stands become somewhat untenable. It is true that all American cements are not as yet wholly suitable for sea water purposes, and perhaps equally true that each and every American concrete engineer has not hitherto insisted

on the proper placing of concrete in salt water structures, not fully realizing the importance of the fundamental principles of the use of concrete in sea water, due to the hitherto limited call for such types of structures in America, lumber having been so plentiful and cheap.

Though reinforced concrete docks have been in existence for more than 15 years, and operated successfully, the same old theorems are still put forth in opposition to them and to the practical experience gained during this period. Possibly these same theories will continue to be advanced against the use of concrete in dock work and other sea structures by the most conservative of our leading engineers, though others, guided and profiting by the experience already gained in such uses of concrete, will continue to expend large sums of money in the further development of such structures.

From a prolonged study of reinforced concrete dock construction, as carried out in foreign countries, it would appear that, in spite of early doubts and skepticism, the success in the use of reinforced concrete in dock work obtained by foreign engineers has swept away all such doubts and skepticism. If these are not facts, why are foreign countries and certain ports in America, including the United States Government, expending vast sums of money in building reinforced concrete docks and in other uses of concrete in harbor development and sea protection work; all "in spite of prejudices which leading engineers [psychologically] have against any new type of construction."

Although the average American contractor may look upon concrete as just so much cement, sand, and stone, or gravel, to be thrown together and dumped into the forms in the quickest possible time, without any regard for the fundamental principles underlying reinforced concrete construction, a commercial proposition purely, such an application of reinforced concrete to dock work will most certainly spell disaster long before the structure is completed.

In spite of its apparent simplicity on dry land, the use of reinforced concrete in dock work calls for more than mere brawn and muscle. It is a class of construction work especially adapted to the broad knowledge, experience, and deep study of the trained engineer in association with an organization well skilled in the handling of concrete in sea water structures—"a field of engineering in which reinforced concrete will prove to be the most permanent and economical, as it has in the building of bridges, etc."

FLOOD FLOWS.
Discussion.*

By Messrs. G. B. Pillsbury and Weston E. Fuller.†

Mr. Pillsbury.

G. B. Pillsbury, Assoc. M. Am. Soc. C. E. (by letter).—Accepting the premise that the magnitude of a flood is due to the combination of an unlimited number of accidental causes, the probability of the occurrence of a flood exceeding a given magnitude should follow the well-established laws of probability as deduced in the theory of errors of observations. Under these laws the probability of an annual flood less than a given value, Q', is given by the formula:

$$P = \frac{h}{\sqrt{\pi}} \int_0^k e^{-h^2 x^2} \, dx \ldots\ldots\ldots\

Mr. Pillsbury.

The usual probability tables give the value of the function, $\frac{2}{\sqrt{\pi}}\int_0^t e^{-t^2}\,dt$, from which the function, $\frac{1}{\sqrt{\pi}}\int_t^\infty e^{-t^2}\,dt$, in Equation 2 can be computed from the relation,

$$\frac{1}{\sqrt{\pi}}\int_t^\infty e^{-t^2}\,dt = \frac{1}{2}\left(1-\frac{2}{\sqrt{\pi}}\int_0^t e^{-t^2}\,dt\right).$$

The author, however, has taken the average value of the annual floods equalling or exceeding the given value as his measure of the expected flood, and not the flood of magnitude which would be derived from Equation 2.

The mathematical expression for this average or mean of floods exceeding Q' is

$$Q = Q\,(\text{Ave.}) + \frac{\frac{h}{\sqrt{\pi}}\int_k^\infty x\,e^{-h^2x^2}\,dx}{\frac{h}{\sqrt{\pi}}\int_k^\infty e^{-h^2x^2}\,dx}$$

$$= Q\,(\text{Ave.}) + \frac{1}{h}\,\frac{\frac{1}{2\sqrt{\pi}}e^{-t^2}}{\frac{1}{\sqrt{\pi}}\int_t^\infty e^{-t^2}\,dt} \quad \ldots\ldots(3)$$

$$= Q\,(\text{Ave.}) + \frac{1}{h}\,M \quad \ldots\ldots(4)$$

It is obvious that this mean value is somewhat greater than its inferior limit.

Table 39 shows the relation between the time, T, considered (or the reciprocal of P in Equation 2), and the value of M (Equation 4).

Mr. Pillsbury.

Taking the floods of Tohickon Creek, as given by the author in Table 4, the computation of the mathematical values of average maximum flood, under the theory of probabilities, is shown in Table 40.

Average = 4 117		$\Sigma v^2 = 2.7027$		$h = 2.11$.

The probable average maximum floods, according to the theory of probabilities, and the observed averages as determined by the author, are plotted on Fig. 14.

Table 41 and Fig. 15 show the floods of the Connecticut River at Hartford for 70 years, beginning 1843. The observed average maximum floods shown on the figure are computed in Table 42.

The floods of the Allegheny River at Kittanning for a 41-year period are tabulated in Mr. Knowles' discussion, Table 33. The value of h, as derived from these data is 2.03. The curve of probable average maxima, the author's curve, and the observed values, are plotted in Fig. 16.

A very cursory examination of the figures shows that, for individual rivers, the observed average maxima differ widely, both from the author's formula and from their theoretical values under the theory of probability. This, indeed, is not extraordinary. The highest of the plotted observed figures is but a single flood, and not an average. The first few of the succeeding observed averages are based on very limited data, and may be expected to differ from their theoretical values in the long run. In the case of Tohickon Creek, the extraordinarily

Mr. Pillsbury.

large value of the maximum observed flood has a very great bearing in the large values of the next lower averages.

The application of the law of probability to the maximum average floods, as given by the writer, is intended merely as a side light on the discussion, it being excessively cumbersome for useful computation. It appears to the writer, however, that the application of the theory to streams with long records shows that the formula of the author will often give far too high values to the flood to be expected in such a long

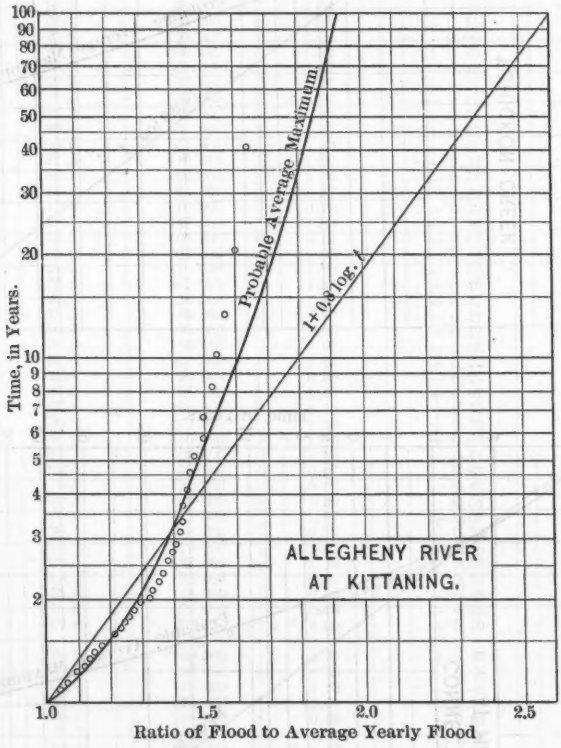

FIG. 16.

period as 1 000 years—which is another term for saying ever expected. Thus, in the Connecticut River at Hartford, the author's formula shows that a flood of 3.4 times the average, or of about 380 000 cu. ft. per sec., is to be expected in a period of 1 000 years. Dropping the somewhat cumbersome average maxima, the theory of probabilities indicates that the chance of a flood twice the average, or 225 000 cu. ft. per sec., is but one in 1 000. Would an engineer be justified in constructing works to care for more than, say, 250 000 cu. ft. per sec.?

Mr. Fuller.

WESTON E. FULLER, M. AM. SOC. C. E. (by letter).—During 1913, and since this paper was written, an unusually large number of disastrous floods have occurred. It is natural that the effect of these great floods on the frequency relation should be discussed and that questions should be raised as to the applicability of the proposed relations to the rivers on which these floods occurred. Several who have discussed the paper have suggested the establishment of different frequency relations for individual streams or for groups of streams.

The writer, in presenting the paper, stated that the formulas proposed were intended to serve "as a frame work on which to arrange the data in an orderly manner, so that they can be better understood and more readily used." With this object in view, formulas were derived which expressed the average frequency relation for the floods which have occurred on many rivers widely distributed over the country. Tables were presented giving values of the coefficient, C, as obtained from the average yearly flood for such rivers as had been observed a sufficient number of years to give an approximate idea of the size of this average. In these tables were also included other values of C, obtained by reducing the larger floods by the use of the proposed formula. These latter values of C indicate how the actual

Mr. Fuller.

floods which have occurred on the rivers have agreed with the proposed formula. The close agreement, for most of the rivers, of these two sets of coefficients indicates that the relation is a general one. During the course of the study on which the paper was based, plottings were made for many individual streams and for groups of streams in different sections of the country. The effect of the few larger floods on the plottings for individual streams was so great that the writer concluded that the relation indicated by them was less accurate than the average relation. Plottings for different sections of the country varied to some extent. If streams in partly arid sections are excluded, the variation of the coefficient of log. T in the formula is from 0.7 to 1. In the extreme cases the number of streams and the length of the records were too short to furnish proof sufficiently strong to justify any change from the general relation. That different frequency relations do exist for individual streams and for different sections of the country is probable, and, as more data become available, such relations may be established.

Great floods which have occurred on the streams in Ohio since the paper was written indicate either that in this section of the country great floods occur more frequently than in other sections, or that these floods were very extraordinary ones. It is unfortunate that so few data are available for floods on the rivers of Ohio, Indiana, Illinois, and, in fact, the streams in all the States along the Mississippi Valley. Floods on streams in adjoining sections indicate that the relation is similar to the average one proposed in the paper. The floods of 1913 in Ohio were caused by rainfall of extraordinary intensity, considering the large area covered, occurring under conditions favorable for great floods. That these conditions were extraordinary is certain, but whether such conditions occur more frequently in this section than elsewhere only the future will show.

Floods of 1913.—Although data are not yet available for all the great floods which occurred during 1913, records of those on some rivers in Ohio and New York have been published. Among those of particular interest are the floods on the Miami River at Dayton, Ohio, the Scioto and Olentangy Rivers at Columbus, Ohio, and the Hudson River at Mechanicsville, N. Y. The data for these rivers, revised to include the records of 1913, are given in Table 43.

The value given for the ratio between the flood of 1913 and the average flood for the streams at Columbus corresponds to a value of T equal to about 1 400. As there are more than 1 400 records of floods on different rivers for which the ratios to the average flood are now available, the occasional occurrence of such a flood is not surprising.

For the Miami River at Dayton, Mr. Morgan expresses the opinion that the coefficient, C, in the writer's formula should not exceed 50. If this were the proper value for C, the 1913 flood on the Miami

TABLE 43.

* Represents rate at maximum stage.

The data for the floods at Columbus are from the "Report on Flood Protection for the City of Columbus" by John W. Alvord and C. B. Burdick, Members, Am. Soc. C. E.

The data for the maximum flood at Dayton are from the discussion by Arthur E. Morgan, M. Am. Soc. C. E.

The data for the maximum flood on the Hudson are from *Engineering Record*, April 12th, 1913, "Effect of Recent Floods on New York Streams" by R. E. Horton, M. Am. Soc. C. E.

River would be relatively very greatly in excess of any flood which we have known on other rivers. The data on which to base the value of C for the Miami are not very satisfactory. In the papers of the U. S. Geological Survey there are 4 years, 1906 to 1909, inclusive, for which floods at Dayton are recorded. An average of these four floods would indicate a value of C of about 86. The best indication of the average flood at Dayton is that deduced from the gauge heights of the U. S. Weather Bureau, which are available for 21 years. As the rating curve for large floods is indefinite, it seems best to obtain the average flood by means of the median gauge height during this period. This has been 11.9, corresponding to a flood of about 39 000 cu. ft. per sec., according to the rating by the U. S. Geological Survey in 1906. During the last 10 years the median gauge height has been 13.25, which corresponds to a flood of about 45 000 cu. ft. per sec. From other rivers it has been found that the median flood is usually less than the average by about 10 per cent. On this basis the average yearly flood on the Miami at Dayton, on the 24-hour basis, under present conditions, is probably at least 45 000, and the value of C is at least 90. The corresponding maximum rate of flow would be 50 000 cu. ft. per sec., or more.

During the past 20 years many changes have been made in the channel of the Miami, such as encroachment on the river channel in cities, and the construction of bridges with long approaches of solid embankment, which greatly reduce the waterway. It seems probable that the coefficient of C for the Miami River at the present time is different from what it was a number of years ago. Mr. Morgan thinks that the Miami should have a comparatively low coefficient of flow on account of the comparatively small average slope of the water-shed. Steep slopes on the upper branches with smaller slopes on the main

Mr. Fuller.

river and lower branches are conditions which may produce larger floods than uniform steep slopes. A comparison of the coefficients for different rivers of the same general character fails to indicate any great effect from the average slope of a river. The writer suggests that the relation between the slopes on different parts of the river and on its branches is of greater importance in determining the flood-producing capacity than the average slope.

The maximum flood on the Miami in 1913 may have been very different in magnitude from the flood which would have occurred if the channel had been unobstructed. The large number of embankments thrown across the valley, with inadequate waterways, provided temporary storage which tended to retard the earlier run-off until the branch streams poured in their maximum flood flows. The subsequent failure of these embankments releasing the stored waters, probably increased the flood materially.

Taking these matters into consideration, together with the great uncertainty of gauging such a flood, it seems probable that the recorded flood flow may have been considerably in excess of the flood which would have come under natural conditions. On the whole, the writer believes that the Miami flood of 1913 was not greater than five times the average yearly flood under present conditions, and that it may have been much less. At all events, the flood was a very exceptional one, and must be given careful consideration in determining the probable floods on our rivers, particularly those in the central part of the country.

The flood on the Hudson River in 1913 is an interesting one, from the standpoint of what may happen on other rivers. The maximum flood on the Hudson, for which records for many years are available, was, previous to this year, much less than what would normally be expected on the basis of its average flood. The flood of 1913, however, not only reached the normal maximum flood for the period of record, but exceeded it by a considerable quantity. There are many other rivers on which the maximum recorded flood is much less than the flood indicated by the average relation. That much greater floods will occur on some of these rivers within a comparatively short period seems assured. As an instance, the greatest flood on record on the Ohio at Wheeling and at Pittsburgh is equivalent to a flood which may normally be expected in a period of not more than 15 years. If a flood of the relative size of that on the Hudson occurs on the Ohio, it will mean a flood of more than 600 000 cu. ft. per sec. at Pittsburgh, or a flood from 4 to 5 ft. higher than the highest now on record.

Reliability of Frequency Relation as Established from Records on One Stream.—Messrs. Knowles, Horton, and Pillsbury give frequency relations for individual streams, which differ from the average relation

proposed by the writer. To show how unreliable such relations may be, Figs. 17 and 18 are presented, which show how greatly one or two of the larger floods affect the relation, even when derived from the longest records available for any stream. Mr. Fuller.

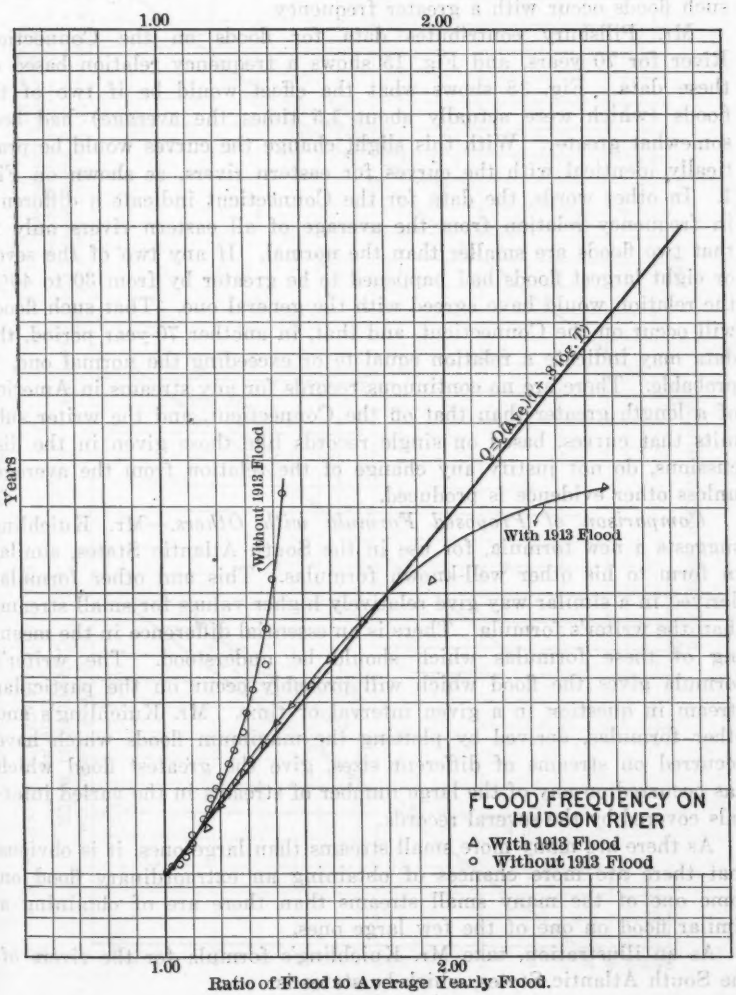

FIG. 17.

On Fig. 17 two curves illustrate the effect of a single great flood. The flood of 1913 on the Hudson is the greatest of which we have record. The effect of this flood is sufficient to change the data so that

Mr. Fuller.

the indications are just the reverse of what they were before the flood occurred. In other words, prior to 1913, the Hudson River records indicated that great floods occurred less frequently than on the average river. By including this flood in the data, the indications are that such floods occur with a greater frequency.

Mr. Pillsbury contributes data for floods on the Connecticut River for 70 years, and Fig. 15 shows a frequency relation based on these data. Fig. 18 shows what the effect would be if two of the floods (which were actually about 1.5 times the average) had been somewhat greater. With this slight change the curves would be practically identical with the curves for eastern rivers, as shown on Fig. 1. In other words, the data for the Connecticut indicate a difference in frequency relation from the average of all eastern rivers only in that two floods are smaller than the normal. If any two of the seven or eight largest floods had happened to be greater by from 30 to 40%, the relation would have agreed with the general one. That such floods will occur on the Connecticut, and that, in another 70-year period, the data may indicate a relation equal to or exceeding the normal one, is probable. There are no continuous records for any streams in America of a length greater than that on the Connecticut, and the writer submits that curves, based on single records like those given in the discussions, do not justify any change of the relation from the average, unless other evidence is produced.

Comparison of Proposed Formula with Others.—Mr. Kuichling suggests a new formula, for use in the South Atlantic States, similar in form to his other well-known formulas. This and other formulas derived in a similar way give relatively higher values for small streams than the writer's formula. There is an essential difference in the meaning of these formulas which should be understood. The writer's formula gives the flood which will probably occur on the particular stream in question in a given interval of time. Mr. Kuichling's and other formulas, derived by plotting the maximum floods which have occurred on streams of different sizes, give the greatest flood which has occurred on any of the large number of streams in the varied intervals covered by the several records.

As there are many more small streams than large ones, it is obvious that there are more chances of obtaining an extraordinary flood on some one of the many small streams than there are of obtaining a similar flood on one of the few large ones.

As an illustration, take Mr. Kuichling's formula for the rivers of the South Atlantic States, which he states is

"based on the greatest observed discharges of the Potomac River at Point of Rocks, Md., the New River at Radford, Va., the Catawba River at Rock Hill, N. C., the Little Tennessee River at Judson, N. C., Cane Creek at Bakersville, N. C., and numerous other streams which

Mr. Fuller.

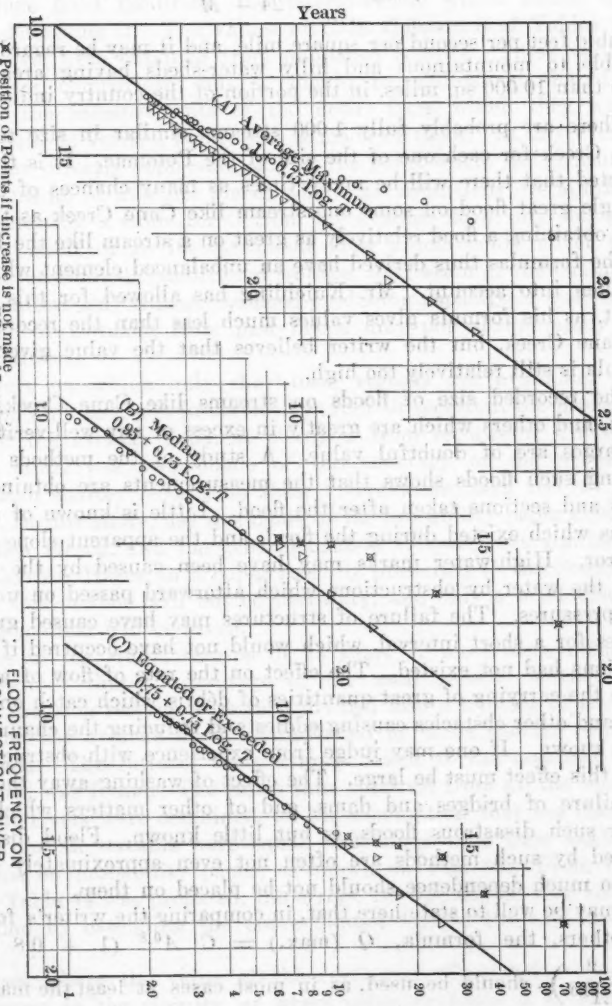

Fig. 18.

Mr. Fuller. exhibit somewhat smaller rates of discharge than the preceding. This new formula is

$$q_{max.} = \frac{41.6\ (620 + M)}{24 + M} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in cubic feet per second per square mile, and it may be regarded as applicable to mountainous and hilly water-sheds having areas of not more than 10 000 sq. miles, in the portion of the country indicated."

There are probably fully 1 000 streams similar in size to that of Cane Creek for each one of the size of the Potomac. It is then to be expected that there will be many times as many chances of obtaining a single great flood on some one stream like Cane Creek as there will be of obtaining a flood relatively as great on a stream like the Potomac.

The formulas thus derived have an unbalanced element which must be taken into account. Mr. Kuichling has allowed for this to some extent, as his formula gives values much less than the recorded flood on Cane Creek, but the writer believes that the value given by the formula is still relatively too high.

The recorded size of floods on streams like Cane Creek, Devil's Creek, and others which are greatly in excess of any well-verified flood discharges are of doubtful value. A study of the methods used in gauging such floods shows that the measurements are obtained from slopes and sections taken after the flood. Little is known of the conditions which existed during the flood, and the apparent slope is often in error. High-water marks may have been caused by the backing up of the water by obstructions which afterward passed on under the flood pressures. The failure of structures may have caused great discharges for a short interval, which would not have occurred if the obstructions had not existed. The effect on the rate of flow of a stream due to the carrying of great quantities of débris which catch on fences, trees, and other obstacles causing eddies and reducing the channel area, is not known. If one may judge from experience with obstructions in pipes, this effect must be large. The effect of washing away the banks, the failure of bridges and dams, and of other matters which occur during such disastrous floods, is but little known. Flood discharges obtained by such methods are often not even approximately correct, and too much dependence should not be placed on them.

It may be well to state here that, in comparing the writer's formulas with others, the formula, Q (max.) $= C\ A^{0.8}\ (1 + 0.8 \log. T) \left(1 + \frac{2}{A^{0.3}}\right)$, should be used, as in most cases at least the maximum rate of flow is given by the other formulas.

Selecting a Value for C.—The selection of the proper value of C is important in the use of the proposed formula. Before its selection, a study of the flood data on the stream in question and on other

Mr. Fuller.

streams of similar nature in the vicinity should be made. This study should be just as complete and thorough as it would be if any other method of determining the maximum flood were to be used. The use of the average flood facilitates the determination where means are at hand to determine it. The values of C in Column 8 of Tables 12 to 26, inclusive, were obtained from published records. These values are useful for comparison, but it should be understood that the accuracy of the measurements of the floods from which they were obtained should be verified before use is made of them. In any event, coefficients are directly applicable only at the point where the measurements were made, or at other places where the conditions are similar.

Before selecting a value for C from the average flood, any changes in the river itself or in its catchment area which would affect the value should be studied. Additional storage, congestion of the channel, and other matters may change the flood-producing capacity of a stream, and a value of C taken from past floods may not always apply to present conditions.

For rivers on which only short-term records are available, the average flood may be much in error. In order to ascertain the probable accuracy of the average flood, as obtained from records of different lengths, a study has been made of the accuracy of the averages obtained from shorter records on those rivers where long records are available. In this study, use was made of the probability paper devised by Mr. Allen Hazen, and the general method followed was similar to that used by Mr. Hazen in a paper recently presented to the Society.* Details of this method will not be necessary, and only a brief discussion of the method will be given.

For use in the study, records of 15 years or more were utilized. It was assumed that the average of the total records is the true average. The long records were then divided into a number of shorter records, and the average flood, as indicated by these shorter records, was obtained. The ratio of these average floods to the assumed true average flood was found. The ratios thus obtained from all the records of different rivers were combined, on the assumption that the chances for errors on all streams were equal. Plottings were then made of these ratios on probability paper, as shown on Fig. 19. From these plottings Table 44 was prepared, the errors, for 20- and 25-year records being found by extending the curve plotted for 5-, 10-, and 15-year records.

In cases where the value of the coefficient, C, is below that of other streams in the vicinity, or where other evidence is at hand to indicate that the coefficient, C, is too low, an increase in the value of C by at least the probable error would be justified. A further increase

* "Storage to be Provided in Impounding Reservoirs for Municipal Water Supply," *Proceedings*, Am. Soc. C. E., November, 1913.

Mr. Fuller. to provide a factor of safety depends largely on the importance of the works under consideration, and on how great a factor of safety has otherwise been provided for in the selection of the value of T.

10	7.5	14
15	5.5	10
20	4.0	7½
25	3.5	6½

Selection of the Value of T.—In the paper the writer has given his views on the method of selecting the value of T. He wishes, however, to call attention to the necessity of using a large value for all important work. The use of a large value of T is much the same as the use of a factor of safety in other engineering works. If we should build structures on a thousand different rivers, using a value of T equal to 1 000, we should do so on the expectation that in each 10 years some five of these structures would be called on to stand a flood in excess of that provided for. For large and important structures, the failure of which would be disastrous, a larger value of T than 1 000 should be used. Where the cost is not prohibitive, providing for floods of from four to five times the average yearly flood does not seem unreasonable for such works.

Mr. Morgan suggests that during some years storms occur which cause great floods on many different rivers, and that this may influence the frequency relation. Undoubtedly more great floods do occur in some years than in others. If the study were based on floods on streams of similar size in one section of the country, the effect of these periodic storms might be great. The writer does not believe that the effect of such periodic storms has materially influenced the proposed general frequency relation, for the following reasons: In deriving the relation, streams of greatly different size are utilized. Great floods on small streams are due to very heavy local storms which do not necessarily affect the largest rivers. The streams considered are widely distributed. During each year, on some streams, floods occur greater than any previously recorded. Some of the records used in establishing the relation go back from 50 to 100 years, and the records are pretty well distributed over the last 20 years. The ten greatest relative floods, as given in Table 9, occurred in eight different years. A study of Columns 7 and 8 of Tables 12 to 26, inclusive, shows no difference in frequency between streams with long and with short records.

Mr. Fuller.

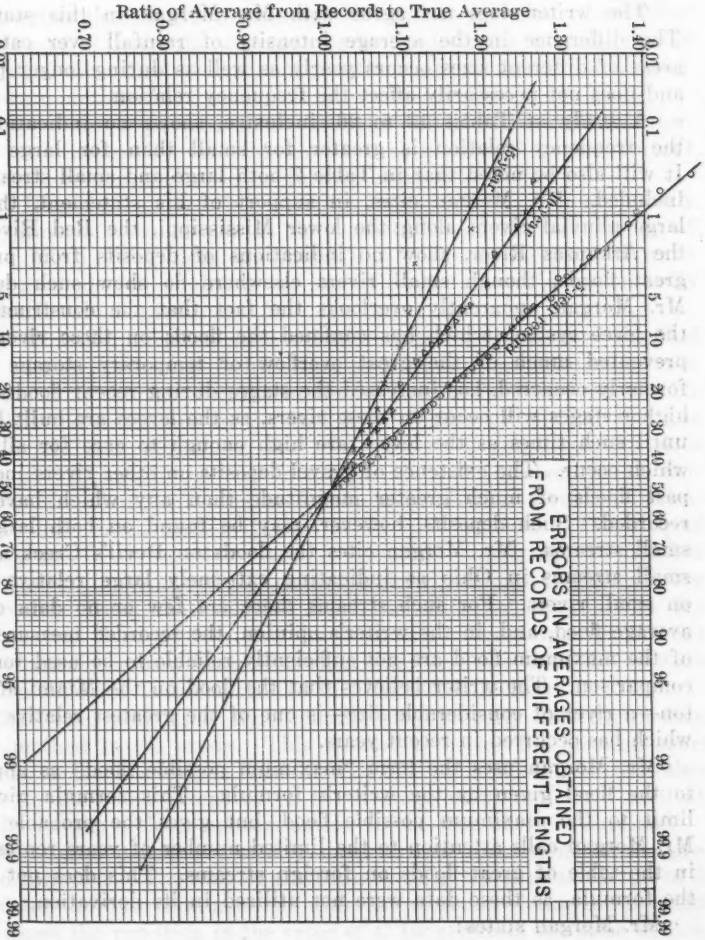

FIG. 19.

Mr. Fuller.

Mr. Morgan states:

"On large water-sheds of 10 000 sq. miles or more, excessive rainfall in one part of the water-shed is usually balanced by lack of rainfall in another part, and the ratio between the average annual flood and the maximum possible flood must be less than for small areas."

The writer does not agree with Mr. Morgan in this statement. The difference in the average intensity of rainfall over catchment areas of different sizes occurs yearly as well as during longer periods, and does not necessarily affect the frequency relation.

A study of Tables 12 to 26, inclusive, shows no indication that the frequency relation is greater for small than for large rivers. It will also be noted that in Table 9 both large and small streams are included. Mr. Morgan cites, in support of his statement, that the large alluvial rivers along the lower Mississippi, the Red River and the Arkansas River, show no indications of deposits from previous great floods, though small rivers elsewhere do show such deposits. Mr. Morgan apparently overlooks the fact that the construction of the levee system, which has confined the floods on these rivers, and prevented much of the great overflow or temporary storage which formerly occurred, has increased the stages during recent floods. Still higher stages will occur on these rivers, as the levees are built higher, until such times as the levees are high enough to care for all floods which occur. The existence of gravel deposits on other rivers indicates past floods of much greater magnitude than any which have been recorded. Such deposits, however, may be found on both large and small streams. Mr. Morgan cites the floods on Devil's Creek and on small streams in Ohio as indicating extremely large relative floods on small rivers. For such streams there are few or no data on the average flood, and, in the writer's opinion, the recorded measurements of the maximum flood are not sufficiently reliable to be used for such comparison. The writer believes that the flood on the Miami at Dayton—a river of considerable size—is one of the greatest relative floods which has occurred in recent years.

Mr. Morgan uses the term "maximum possible flood" as applying to the flood given by the writer's formula. This formula gives no limit to the maximum possible flood, but gives the probable flood. Mr. Morgan calls attention to the limited number of years represented in the table of great floods on foreign streams. This does not affect the formula, as these data were not utilized in its derivation.

Mr. Morgan states:

"It might be better to estimate the maximum possible flood by what might be called the rational method, that is, by determining from the basis of experience and the maximum rainfall to be expected, the relation of rainfall to run-off under the conditions which would exist in an assumed case, considering the elements of topography, shape of the drainage basin, direction of storms, season of the year, etc."

Mr. Fuller.

There is quite as much uncertainty in probable maximum rainfall as in probable flood flow. There is, in addition, great uncertainty as to the percentage of run-off to be expected on different rivers, and under different conditions. We know but little of the effect of topography, direction of storm, shape of catchment area, and other factors. To the writer there seems to be much less chance for error in selecting the value of C from the average yearly flood, or by a study of the values of C for other rivers, than in estimating values for these many unknown quantities.

Many of the important points brought out in Mr. Morgan's interesting and instructive contribution have been covered in the writer's general discussion, and need no further comment.

Mr. Hinckley's interesting remarks, made in 1911, indicate clearly how engineers have looked at the probability of the occurrence of floods. His rainfall data are interesting. The application of probability methods for obtaining the probable rainfall would undoubtedly give much valuable information.

Mr. Chandler presents some valuable data for the flow of the Red River of the North and its branches, and draws some interesting conclusions as to the frequency relation of streams in that section. He says that the conditions in the Red River Valley are similar to those in a partly arid region, so that the writer's average relation does not hold. Although the data available are not sufficient to be conclusive, Mr. Chandler's suggested frequency relation gives an indication of how much higher it may be in such sections. The size of the average flood for such rivers is governed largely by the number of dry years in the period. It occurs to the writer that in determining the average flood, the exclusion from the record of all years so dry that no real flood occurs, may have merits, thus giving an average of the real floods as a basis of comparison. On this basis the relation may be expected to be more like that for other sections.

The writer notes that Mr. Chandler very properly uses the median flood method in his study. This method is better for plotting short records, as the few largest floods do not affect the plotting of the other floods to the same extent as in the average maximum flood method, and by its use a closer approximation to the true curve is obtained.

Mr. Hazen points out clearly the uses and limitations of the proposed formulas. The map of the country (Fig. 7) is most useful, as it indicates the data available for different sections of the country and also shows the variation in the value of C for rivers in the same section. A study of the conditions will in most cases account for such variations. For instance, in Maine, where the coefficients vary from 17 to 110, it will be found that the low coefficients are for small streams draining extensive systems of lakes which control largely the floods, and the large values are for streams on which there is little or no storage.

Mr. Fuller. It is interesting to study the effect of this storage on the river system. For the upper branches, the effect is great, but, as the streams join to form the larger rivers, the effect decreases rapidly until, near the mouth of the river, the coefficients are in some cases several times as great as for the upper branches. The study of streams in that State, where there are such extensive lake systems, is most illuminating in regard to storage for flood protection.

As Mr. Hazen states, probability paper might have been utilized in the study of flood frequency. During the study for this paper the normal probability curve was tried, but it was found that the data did not fit it as closely as the logarithmic curve adopted. The use of probability paper, which provides a ready means of drawing curves varying somewhat from the normal law, allows this method to be used. Practically, however, such a curve would give results identical with the formula, within the limits of the data, and an extension of the curve would indicate a ratio of 4.0 for $T = 10\,000$, as compared with 4.2 by the formula. Such differences are of little moment, and no data are available to indicate which is the more nearly correct.

The method of plotting gauge heights on probability paper, as suggested by Mr. Hazen, should prove useful. The writer has plotted records of the gauge heights for many stations along the Mississippi and its branches. Although these plottings are not in all cases as close to a straight line as the one for Cincinnati, they all approximate such a line. Within such limitations as may be applied by one having a thorough knowledge of the river, both as to changed conditions affecting the stages and as to the storage and increased channel capacity which occur at higher stages, this method seems applicable to many rivers.

Mr. Hazen's suggestion in regard to determining coefficients of variation, as an index of how closely the stream follows the average law of frequency, is interesting. It may be that a thorough study of the regularity of flow throughout the year, and of other characteristics of the stream, would enable the effect of some factors on flood frequency to be ascertained.

Mr. Knowles, citing a record of a single stream as an indication of variation from the average, warns against the general use of the average relation. The writer pointed out in the paper, and has further stated in this discussion, that a thorough study of all local conditions should be made before using the formula, but must repeat that, in his opinion, the data on a single stream are entirely inadequate for establishing a frequency relation. It could be shown by a plotting similar to Fig. 18 that the data for the Allegheny River at Kittanning really differ but slightly from the average relation. Mr. Knowles' extension of the existing record to a 41-year record, by estimating the flood at Kittanning from the gauge height at other points on the river

is of doubtful accuracy. An examination of Figs. 10 and 11 will show that the actual floods which Mr. Knowles plotted in order to obtain the curves showing the relation between the gauge heights at Kittanning and those at Freeport and Parker differ, in some instances, by from 50 to 100% from the curves. If these actual floods do not agree more closely with the curves, it is obvious that similar errors probably exist in the floods obtained in this way and included in the record. As the effect of the few large floods is so important, it is clear that a record obtained by such methods should not be used in discussing frequency. Mr. Fuller.

Mr. Bellamy's discussion is interesting, and gives much valuable information as to flood flows in Australia. The large variation in floods for the different rivers is to be expected in a country so large and with such widely varying conditions. As Mr. Bellamy states, a comparison of such rivers, with the limited data available, is very unsatisfactory. It is much the same as comparing rivers of the American coast, where the coefficients are in many cases greater than 100, with rivers in the Missouri River Basin or the Great Basin, where the coefficients are in many cases less than 10.

Mr. Kuichling has supplied tabulated data relating to great floods which have occurred on both foreign and American rivers, and these, taken in connection with those previously presented by him, give by far the most complete record of maximum flood flows available. The data from which this information was prepared are widely scattered. In many cases, particularly for foreign streams, the original data are in such a state that most careful study of them is required before they can be used. The collection and analysis of this large mass of data should be appreciated by all who are interested in the flood problem.

Mr. Kuichling brings out clearly many important aspects in regard to flood flows. Some of these points have been taken up by the writer in the preceding general discussion, and need no further comment.

Mr. Kuichling calls attention to the wide variation in the value of C for different rivers in the same general section of the country, and suggests that it may be better to use a single value of C for one section. Where coefficients are based on long records, the writer believes that the differences in the values of C indicate different flood-producing capacities for the streams. In many cases these differences may be accounted for by a study of the catchment area, as to slopes, storage capacity in lakes, and rainfall conditions. Where records of considerable length are not available, the writer agrees with Mr. Kuichling that much consideration should be given to the coefficients for other streams in the section. He is correct, in his interpretation of Tables 12 to 26, inclusive, in stating that the values of C in Column 8 were the ones intended for general use. The values in Column 8 are derived from the average flood, and take into account all the largest yearly floods in the rivers; they are more accurate than those in Col-

Mr. Fuller.

umn 7. It would have been better, as he suggests, to have called these C_1 and C_2.

Mr. Kuichling calls attention to the important work of Iszkowski, and reduces his formula to conditions for the United States. Although this formula is of very different form from the writer's, it may be of interest to show how the results obtained from it agree with those obtained from the writer's formula,

$$Q\ (\text{max.}) = C\,A^{0.8}\,(1 + 0.8\ \log.\ T)\left(1 + \frac{2}{A^{0.3}}\right).$$

Under what may be regarded as similar conditions, Iszkowski's formula differs from the writer's by the following percentages: for a catchment area of 10 sq. miles, — 21%; 100 sq. miles, + 32%; 1 000 sq. miles, — 2%; 10 000 sq. miles, — 39 per cent. This comparison is made on the basis of the values deduced by Mr. Kuichling from Iszkowski's formula for "hilly country, slightly permeable soil, and sparse vegetation" and of a use of $C = 100$ and $T = 100$ in the writer's formula.

The writer has plotted the largest of the floods in America, as given by Mr. Kuichling, on the lower diagram of Plate LXIX, and finds that with the exception of three or four extreme floods, such as those on Cane Creek and Devil's Creek, the plottings agree with the curves representing the writer's formula as well as the points previously plotted.

Mr. Horton calls attention to a discussion of the use of probability methods in a report made by Mr. Rafter in 1896. This discussion is interesting and instructive. That paper, however, is entirely confined to a discussion of rainfall and minimum run-off. The writer fails to find any suggestion as to the use of similar methods for determining flood flows. Until Mr. Horton called his attention to it, the writer was not aware of the existence of this study. Mr. Horton further states that Mr. Rafter suggested to him the use of probability methods for determining the probable flood as early as 1896 and that he has used it on numerous occasions in his professional work. The writer had no means of knowing about any work which Mr. Horton had done on this subject, and sees no reason why he should qualify the statement that the original suggestion came to him from Mr. Hazen.

Mr. Horton gives three different formulas derived from the data on rivers near Philadelphia. He also gives the following general formula for which he states that he

"does not claim any great breadth of applicability for the general formula, * * * but believes that factors other than area modify the flood discharge of streams so profoundly that it is better, wherever possible, to derive individual formulas or flood-frequency diagrams for each stream."

Mr. Fuller.

This formula is:

$$Q = 4021.5 \frac{T^{\frac{1}{2}}}{A}$$

in which Q is the flow in cubic feet per second per square mile. To put this formula on the basis of the writer's, that is, to give the total flood flow of the stream, it becomes necessary to multiply by A, so that the formula becomes

$$Q = 4021.5\ T^{\frac{1}{2}}$$

According to this formula, the maximum floods to be expected are independent of the catchment area. Surely a formula which does not take into account the size of the catchment area can have no general application.

During the early part of the study for this paper, exponential formulas such as those proposed by Mr. Horton were tried. It was found that though these gave curves closely following the data for short periods, for the longer records the exponential relation was less satisfactory than the logarithmic relation adopted.

The writer deems it unfortunate that, after seventeen or more years of consideration of the use of probability methods for the determination of flood flows, Mr. Horton should have confined his discussion so largely to criticizing details of the writer's methods, instead of giving more in regard to his own studies.

Mr. Horton states:

"It would appear that the relation between flood magnitude and frequency, when expressed in terms of either 'average maximum flood' or 'median flood,' is not only very indefinite and difficult of comprehension, but is apt to be very misleading, if it is not indeed practically meaningless. It does not directly convey the information which the engineer usually most desires, for example: If a spillway has a capacity of 1 000 cu. ft. per sec., how often on an average will its capacity be exceeded?"

In regard to this statement, the writer will call attention to the fact that the others who have discussed the paper have not found the proposed formula either indefinite or misleading, but, on the contrary, have comprehended its true meaning. The writer, on pages 1022-1029,* described three different methods which are applicable to flood frequency problems. In Table 6 the formulas representing these methods are stated, and values are given for the volume of the flood indicated by them in different periods of time. If any one wishes to know the volume of the flood that will probably be equalled or exceeded in a period of time, he may do so by using the formula:

$$Q \text{ (equalled or exceeded)} = C A^{0.8} (0.7 + 0.8 \log. T)$$

* *Proceedings*, Am. Soc. C. E., May, 1913.

Mr. Fuller.

as given in Table 6. There are problems in which it is useful to know the volume of this flood, but the writer believes that the most important question which the engineer desires answered is: What is the probable flood for which to design our structures? For this purpose we surely do not wish to ascertain the smallest of the maximum floods that is likely to occur in the given interval, which is only a different way of stating the "flood to be equalled or exceeded." For example, suppose we have a record which includes ten periods, each of 20 years. Each of these periods would have a maximum flood of a different size. The flood to be equalled or exceeded in a 20-year period would be the smallest of these. To design works which would just provide for this flood would mean that in all probability the design would prove inadequate within the period, because during nine out of ten periods, greater floods would occur.

The average of the ten maximum floods which have occurred in the several periods, as given by the writer's formula, seems to be a logical basis for design in order to provide for a reasonable chance that the structure will survive the given interval. The median of these floods, or the one for which there is one greater for each one less, represents the flood for which the chances are even that it will occur in the given period. The use of this flood is as logical as the use of the average. The difference in value between the two is slight, and the writer, for the reasons stated in the paper, prefers the average maximum.

Mr. Horton, after giving a method of determining the "average interval of recurrence of a flood lying between any two given magnitudes", states: "This illustrates what seems to be a fatal error in the author's method of analysis."

The writer fails to find in the paper any statement which would justify the interpretation Mr. Horton has given the formula. As the method of derivation and the meaning of the formulas are explained in considerable detail in the paper, the writer considers that to apply it as Mr. Horton has done is entirely unwarranted. If the determination of the average interval of recurrence of floods of a size between fixed limits is desirable, as it may be for some special problem, the use of the flood to be equalled or exceeded, as suggested by Mr. Horton, is proper. Such use, however, is an unusual one, and to find a "fatal error" in the average maximum flood formula because it is not applicable to such a problem, is like condemning a formula proposed for determining the strength of a steel beam because it does not give the deflection of the beam. The writer was aware that the "flood to be equalled or exceeded" and the "median flood" had their uses, and accordingly gave the formula by which they might be obtained and descriptions of the methods of derivation, but, to

Mr. Fuller.

explain their application to special problems, he thinks is beyond the scope of the paper.

Mr. Horton considers the use of ratios "confusing and cumbersome". By the use of ratios it becomes possible to compare the frequency of occurrence of floods on different rivers, which, in the writer's opinion, is of the greatest importance.

Mr. Horton objects to the writer's method in that he does not use all the floods to determine the frequency relation. As a matter of fact, in the determination of the general formula, 1 672 floods were considered; 20 of the largest were plotted individually and 200 others in groups of ten. This plotting covered three-quarters of the total length of the curve, as plotted in Fig. 1. It is apparent that, with the average maximum method, the average flood, which has a ratio of unity, must be plotted for 1 year. A straight line drawn from unity through the average of the points plotted satisfied the requirements, thus making the plotting of the remaining points so obviously unnecessary that it was not done. The writer assures Mr. Horton that the remaining points will fall close to the line. Mr. Horton's other criticisms of the paper are, the writer believes, fully covered by the foregoing discussion.

Mr. Pillsbury's discussion is an interesting and natural one. An examination of Fig. 18 shows how a slight change in the data on the Connecticut River would affect the frequency relation, and the writer has already given his views on the reliability of frequency relations established from the records of single streams. Aside from this, the assumption made by Mr. Pillsbury contains a fundamental error which would have to be, and could be, eliminated. This error is in assuming that the series of annual floods follows the normal law of probability. By the normal law of probability, the variations upward and downward from the normal are equal. As a matter of fact, with flood data, the variations upward and downward are not equal. The variations downward are more numerous, but the variations upward are greater in magnitude. The values follow, not the curve of normal probabilities, but what is called a skew curve. If Mr. Pillsbury will deduce the formula that most accurately represents this skew curve, and will show its application, he will give a useful solution of the problem which he has attempted, and will be doing the Profession a real service.

CONCRETE BRIDGES: SOME IMPORTANT FEATURES IN THEIR DESIGN.

Discussion.*

By Messrs. W. D. Maxwell and Walter M. Smith, Sr.†

Mr. Maxwell.

W. D. Maxwell, Assoc. M. Am. Soc. C. E. (by letter).—The question of temperature changes in arches has been mentioned by several who have discussed this paper.

When the Walnut Street Concrete Bridge, of which the writer was one of the designers, was built in Des Moines, Iowa, in 1911, nine electrical resistance thermometers were embedded at various points in one of the arches. This arch has a clear span of 68 ft., a crown thickness of 16 in., and a solid spandrel fill. The greatest range in temperature was at the crown, where an average of two thermometers showed a temperature of 86° Fahr. about 16 hours after pouring, 9° below zero as the low point during the following winter, and 86° in the summer of 1912, one year after the bridge was built. Other thermometers placed in thicker portions of the arch showed somewhat less susceptibility to atmospheric changes. The average of two instruments embedded about 2 ft. in heavy concrete near the pier and abutment showed 98° Fahr. about 36 hours after pouring, 20° the next winter, and 85° the following summer. The average of all the thermometers for the first 6 months, gave a range of temperature in the concrete of 87.6 degrees. The upper limit of this range was the extreme produced by the heating of the setting concrete. The average of all the thermometers for the second 6 months was 79.2 degrees.

The extremes of atmospheric temperature in the summer of 1911 and the following winter were very great for this locality, the total

*Continued from February, 1914, *Proceedings*.

†Author's closure.

Mr. Maxwell.

range being 135 degrees. However, ranges of considerably more than 100° may be expected every year.

Elevations were taken on all six arches of the bridge in September, 1911, when the average of all the thermometers was 75°, and again in January, 1912, when the average was 11 degrees. The difference corresponded closely to that computed for a change of 64° in the temperature of the concrete.

In the design of the bridge, allowance was made for a 40° rise, and a 40° fall. These amounts were considered excessive by some engineers, but the actual observations show that they were not only not too small, but that the fall was more than 40°, the concrete having been poured at a general average of about 70 degrees.

Considering these temperature ranges, it is apparent that concrete bridges built in these rigorous climates, especially the hingeless arches, must be very carefully reinforced against temperature stresses, and it is also evident that the warmer climates and those having nearly uniform yearly temperatures possess a real advantage with this type of construction.

Mr. Smith.

WALTER M. SMITH, SR., M. AM. SOC. C. E. (by letter).—Mr. Gregory states that the decision to adopt a three-hinged arch for the Traver Hollow Bridge was taken because the foundations for the abutments and piers would be on compressible material. He also states that the preliminary estimates indicated that the three-hinged arch would be somewhat more expensive than the fixed-arch type. He is correct in the first statement, but is mistaken in the second. Only a rough estimate was made for a fixed arch at this site, making certain assumptions as to the depth to rock. Careful designs and estimates were then made for a three-hinged arch, to compare with the other. The writer had charge of both estimates, and made the design and estimate for the three-hinged arch. He has copies of these estimates before him as he writes. If the same unit prices are taken for the three-hinged arch as for the fixed arch, the saving would be about 30% for the former. Therefore the average increase in unit price for the three-hinged arch would have to be 43% in order that it might cost as much as the fixed arch for this site. When these estimates were obtained, as there was no information at hand as to the depth to rock, it was decided to build the three-hinged arch, as it was certain that the material would carry the load of an arch of this type by compressing slightly, and would not injure the arch.

Figs. 10, 11, and 12 show the details of the hinges and the method of connecting them to the steel ribs of the arch. It will be seen that the steel forms a continuous structure between the abutment hinges, with an additional hinge at the crown.

When the design of the Rye Outlet Bridge was under consideration, the writer also investigated a three-hinged arch for this site, at Mr.

Mr. Smith.

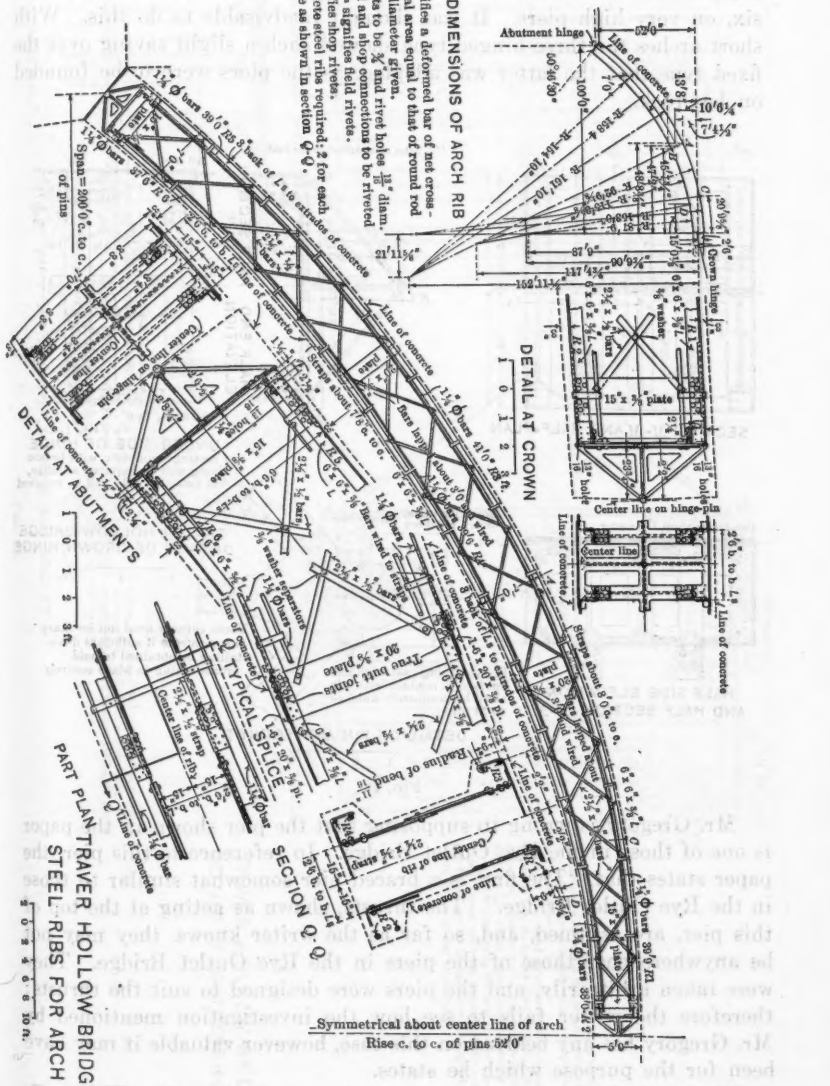

FIG. 10.

Mr. Smith.

Gregory's request. As the height of the roadway was fixed, and also the water line, the design was limited to short arches, unless it was admissible to construct them with a ratio of rise to span of more than six, on very high piers. It was thought inadvisable to do this. With short arches the three-hinged type showed such a slight saving over the fixed type that the latter was adopted, as the piers were to be founded on bed-rock.

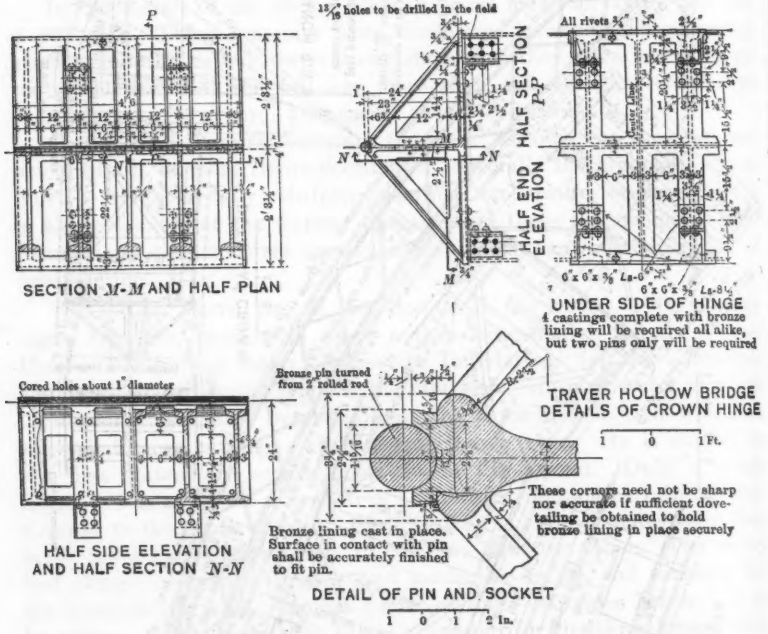

FIG. 11.

Mr. Gregory is wrong in supposing that the pier shown in the paper is one of those in the Rye Outlet Bridge. In reference to this pier, the paper states that, "The first is a braced pier somewhat similar to those in the Rye Outlet Bridge." The thrusts, shown as acting at the top of this pier, are assumed, and, so far as the writer knows, they may not be anywhere near those of the piers in the Rye Outlet Bridge. They were taken arbitrarily, and the piers were designed to suit the thrusts; therefore the writer fails to see how the investigation mentioned by Mr. Gregory has any bearing on this case, however valuable it may have been for the purpose which he states.

The method of constructing an arch, described by Mr. Wilson F. Smith, is a very satisfactory one, if the arch is to be of plain concrete,

Mr. Smith.

DETAILS OF ABUTMENT HINGE

FIG. 12.

Mr. Smith.

but, with all due respect to Mr. Janni, who states that he has constructed reinforced concrete arches in this manner, the writer cannot believe that it is economical. The difficulty of fitting the great number of bulkheads around the steelwork is very great, and the expense very heavy. In Pittsburgh, Pa., a reinforced concrete bridge, with a main arch of 216 ft., consisting of two separate ribs, is now being built by this method. With slight modifications, the same method has also been used extensively in America, and also in Germany, for plain concrete arches, and has proved very satisfactory.

The main arches of the Walnut Lane Bridge, in Philadelphia, Pa.,* were built in sections, leaving spaces between many of them to be filled with concrete later, as keys. Mr. Janni states that he has used the same method.

The arches of the Connecticut Avenue Bridge, Washington, D. C., were also built in sections, the spaces between the sections being filled in afterward, but this bridge and also that at Walnut Lane were of plain concrete, and in neither case was a temporary hinge made at the abutment or crown, as in Mr. Morison's method.

On the other hand, many masonry bridges in Germany have been built with temporary stone hinges at the crown and the abutments to insure the passage of the equilibrium polygon through these points for the dead load, the spaces around these hinges being filled with concrete on the completion of the bridge.

Mr. Quimby and Mr. Mensch state that, in the fixed arch and the three-hinged arch, the thrust at the crown is about the same, and therefore Mr. Quimby reasons that the thickness of the crown should be about the same, seeming to forget the fact that, for a heavily unbalanced live load, the thrust at the crown does not pass through the center, though in the three-hinged arch it is compelled to do so. In the Rye Outlet Bridge, which was designed for very severe conditions—a 20-ton road roller concentrated on one rib—this was especially so. At the crown the thrust was about 5 in. from the center; at the abutments, it was more than 12 in.; thus it was necessary to have a thickness of at least 30 in. at the crown and more than 6 ft. at the abutments in order to keep the equilibrium polygon in the middle third. As a matter of fact the thrust at the crown is slightly less in the three-hinged arch, on account of the difference in weight of the arch itself, but the great difference is caused by the thrust being central in the latter case. In the Rye Outlet Bridge, if three-hinged, only a thickness of 20 in. is needed at the crown and 25 in. at the abutments, as the thrust passes through the center at both places, and that at the abutments is only 25% greater than that at the crown.

---

* "Walnut Lane Bridge, Philadelphia," by George S. Webster and Henry H. Quimby, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXV, p. 423.

Mr. Smith.

The point made by Mr. Quimby, that thickening the arch to keep the equilibrium polygon within the middle third will increase the temperature stresses on account of the added stiffness, is well taken, and this is one of the main objections to the fixed arch. How is this trouble to be remedied? Some engineers do so by assuming much less temperature change than the writer believes to be justifiable, thus letting the concrete crack and cause some kind of a hinge of its own if its strength is exceeded. Others do so by allowing higher unit stresses in the steel and concrete. Apparently, Mr. Quimby prefers the former method, judging from his statement of what he believes to be the maximum temperature variation in concrete.

The cracking of the concrete at the abutment or crown, or both, which occurs frequently in fixed-arch bridges for which a sufficient variation of temperature has not been allowed, will not necessarily endanger the arch. It is merely an attempt, on the part of the concrete, to remedy the fault of the designer, and form hinges of its own, thereby readjusting the stress. These cracks, however, are unsightly, and, when they occur, it is hard to convince the layman that the bridge is still safe.

The writer has stated that, with regard to appearance, the three-hinged arch is at a disadvantage, and, when the question of beauty is of sufficient importance, it would probably not be considered, its advantage being where economy is of first importance.

The maximum range of temperature change in an arch is not necessarily the change from midsummer to midwinter, with the condition of "no stress" lying midway between. Unless the arch is built in the spring or fall, and some method (such as that described by Mr. Janni) is adopted to eliminate the stresses due to setting shrinkage by leaving in the arch key spaces to be filled in after the concrete of the arch has been placed, set, and cooled off, this range will be much higher. If these precautions are not taken, the condition of "no stress" in the arch is the position it occupies at the setting temperature of the concrete, and any variation from this position causes deformation of the arch, and, therefore, stress. The variation will be all one way if the bridge be built in the summer. The steel in the arch has no effect in preventing cracks in the concrete, in fact, it generally causes them to occur more quickly than if it were not used. Many engineers have had this experience in building various structures. In building the retaining walls for the Pennsylvania Railroad terminal, in New York City, it was found to be impossible to make the length of the sections of wall greater than 25 ft. without cracks.* The reinforced concrete floor beams, which carry the concourse floor of vault light construction in the Pennsylvania Railroad Station, New York City, show cracks where they join the columns at almost 50% of the points. These were built as continuous beams over great distances, and the setting shrink-

* *Transactions*, Am. Soc. C. E., Vol. LXVIII, p. 334.

Mr. Smith.

age caused the cracks. The beams are not necessarily unsafe because of these cracks.

In 1908 a high, heavily reinforced concrete retaining wall was built along the railroad yard on the water-front at St. George, Staten Island. It is several thousand feet long, and was built without expansion joints. In the fall of that year the writer was informed, by one of the most prominent engineers connected with this work, that expansion joints had not been provided as they were not needed, the quantity of steel being sufficient to prevent it from cracking. The writer had seen some of the effects of this before, so in March, 1909, he inspected carefully about 1 000 ft. of this wall, and in that length counted 45 cracks extending from the base to the top, and 17 extending part way, making an average of about one crack in every 16 ft. Through 8 of these cracks water was issuing at various heights.

A similar experience was had in the top of the Cross River Dam. George G. Honness, M. Am. Soc. C. E., Division Engineer in charge of its construction, states that:*

"It was not expected that the use of these rods would entirely eliminate the temperature cracks, but it was hoped that it would prevent their concentration in a few large cracks.

* * * * * * *

"The reinforcement * * *—as to quantity and method of placing—was not effective in preventing the concentration of the cracks."

The following is given as an example of how greatly concrete shrinks in setting. On some work with which the writer was connected, some years ago, it became necessary to cut out some concrete in a ceiling consisting of a very deep and heavy concrete slab with reinforcing bars embedded about 2 or 3 in. from the lower surface. The concrete was cut from around a few of these bars for a distance of about 2 ft. All the bars, when released, sprang out of line, thus showing that the shrinkage of the concrete, in that short distance, was sufficient to shorten the steel bars by compressing them. Theoretically, these bars were carrying a tension of 16 000 lb. per sq. in. In reality, they were in compression, and the concrete was not only carrying all the load, but was also compressing the steel.

Many experiments have been made in order to determine the rise in temperature in cement mortar, neat and of various compositions, and of concrete during setting. In some tests by the Universal Portland Cement Company on neat cement cubes, the average temperature rise was from 80° to a little more than 130° Fahr., in from 6 to 8 hours after placing. In the case of concrete, the initial temperature, 70° Fahr., was increased to 80° in 8 hours, 100° in 25 hours, and 105° in 45 hours. Tests in the laboratory of Lehigh University have shown

* *Transactions*, Am. Soc. C. E., Vol. LXI, pp. 411-413.

Mr. Smith.

that the temperature of an 8-in. cube of 1:3 Portland cement mortar rose from an initial temperature of 70° to 160° Fahr. in 18 hours. At the Watertown Arsenal, a few years ago, tests of 29 cubes of neat cement, representing 27 brands of cement, were made. The initial temperature was 77°, and the average maximum 185° Fahr., showing a rise of 108° in an average of 13 hours. The thermophones embedded in the cyclopean masonry of the Boonton Dam indicated a rise of from 20 to 25° Fahr., although only about two-thirds of the mass consisted of concrete. In the locks of the Panama Canal the rise was also about the same.

Table 1 shows the setting temperature in some concrete canal walls at Madison, Me., built for the Hollingsworth and Whitney Company. As the concrete was placed in the winter, it was first heated to 70° Fahr. The average atmospheric temperature was 11° and that of the concrete 108°, showing a rise of 38° after being placed, in spite of the exceedingly low outside temperature.

As an example of the low temperature which may be reached in bridge arches in the Northern States, Table 2, showing the results of tests on the Squaw Creek Bridge, at Ames, Iowa, is interesting.

Mr. Maxwell has given a brief account of the range of temperature experienced in the Walnut Street Bridge, Des Moines, Iowa, and

Mr. Smith.

readers are referred to a synopsis of his original report on this bridge, and also on some others.* Many of the data herewith presented have been obtained from Mr. Maxwell's valuable report. Tables 3 and 4, taken from that report, are interesting.

center of the pier, Nos. 6 and 7 in the center of the arch halfway between the springing line and the crown, and Nos. 8 and 9 in the center of the arch at the crown. The arch is not exposed on its upper side, as there is an earth fill above it. Coils Nos. 6 and 7 are about 9½ in. from the surface, and Nos. 8 and 9 about 8 in., consequently the heat generated by the setting would be dissipated much more rapidly at Nos. 6, 7, 8, and 9, than at the others. Conversely, these four reach temperatures much lower in winter and somewhat higher in summer than the others. As the upper surface of the arch is protected by an earth fill, the range there is probably not as great as it would be if the arch had open spandrels, therefore the variations are on the conservative side.

It is evident, in this case, that the concrete set and the arch took its shape at a temperature of more than 90 degrees. Any deviation from this temperature, then, would cause stress in the arch. As all the thermometers in the arch itself reached zero, or went below zero, during the following winter, the arch was subjected to a stress due to a variation of more than 90° from the normal. The arch was designed for a variation of 40° each way from the normal, therefore it was subjected to 2¼ times as great a range as that for which it was designed. What is likely to happen in such a case? Probably the arch will crack, either at or near the abutments, or at the crown, or at both. As the arch at the abutments or piers is much deeper, and therefore much more rigid, than at the crown, the cracks are more likely to appear there. When the concrete cracks the stress is readjusted, and the arch has formed somewhat of a hinge for itself. As stated previously, the arch is not necessarily endangered by these cracks, as they cause a readjustment of the stress, but they are unsightly, and it is difficult to convince a layman that the arch is perfectly safe.

In his report Mr. Maxwell states that at that time there were no

Mr. Smith.

cracks in the Walnut Street Bridge, but in the Squaw Creek Bridge there are unsightly cracks at the exact point of computed maximum stress at three of the four corners of the bridge. He also states that in the Locust Street Bridge, Des Moines, Iowa, there are cracks at the crown of each of the shore spans.

As all these arches were designed for a variation of 40° each way from the normal, Mr. Maxwell concludes that for northern latitudes a variation of this much should be allowed, and that:

"Particular circumstances may demand that a greater variation be used for drop in temperature to prevent the appearance of cracks."

This conclusion was reached by the writer some years ago. If, in the face of these facts, an engineer is willing to design a bridge for a variation of only 20° each way from normal, as Mr. Quimby seems to propose, and then lets the bridge crack and form its own hinges, the writer freely admits that it will be a cheaper bridge than a three-hinged arch designed for reasonable stresses.

It is admitted that, if a stone hinge be used in an arch, the friction of the hinges should be taken into consideration in computing the stress due to change of temperature, but with a metal hinge, such as that in the Traver Hollow Bridge, the amount would be so small as to be negligible. The writer would like to call Mr. Janni's attention to the details of these hinges and the arch rib, Figs. 10, 11, and 12. He will see that the span of the arch is 200 ft., and that the diameter of the pin at the abutment hinge is about 3 in., and at the crown 2 in.; therefore the maximum deviation of his lines, P_1 and P_4, would be 10 in. in 110 ft., which is certainly not very serious, to say the least. The pressure on these pins is about 12 000 lb. per sq. in. The socket for holding the pin is very heavy and rigid so as to cause very nearly an even distribution of pressure on the pin and a lining is cast in the socket and then finished to fit the pin accurately. The metal of the body of the hinge is cast steel having an elastic limit of 40 000 and a tensile strength of 76 000 lb. per sq. in., an elongation of 20% in 2 in., and a reduction of area of 41.5 per cent. A sample of this steel, ½ in. thick, was bent 180° around a diameter of 1½ in. without a sign of cracking either on the outside or inside of the bent portion. The socket of the casting was lined with "Monel" metal by casting it in place and then machining it to fit the pin accurately. The pin was of the same metal, finished from a rolled bar. This metal is a natural alloy of approximately the following composition: nickel 68%, copper 31%, and iron 1 per cent. The writer has a sample of this metal which tested as follows: tensile strength, 100 000 lb. and elastic limit 71 600 lb. per sq. in., elongation, 35% in 2 in.; reduction of area, 54.7 per cent. Now, with this metal as a bearing for the hinges, even if there was the concentration of pressure which Mr. Janni thinks is so serious,

Mr. Smith.

there would still be a factor of safety of 3 on the elastic limit of the material, and this, the writer thinks, is sufficient.

For the bending moment due to friction on the pin, the coefficient of friction of the pin and lining may be assumed at 0.20. The best authorities give this coefficient, for metal on metal, dry, as from 0.15 to 0.25; and, as this bearing is bronze on bronze, it will probably be nearer the lower limit, so that 0.20 should certainly be conservative. The total pressure on the pin is about 2 000 000 lb., therefore the bending moment of the friction at the surface of the pin, with the lever arm of 1½ in., will be $2\,000\,000 \times 0.20 \times 1.5 = 600\,000$ in-lb., which would be the moment caused by the pressure line deviating from the center line by less than 0.3 in., as the pressure decreases as the distance from the pin increases.

Mr. Janni speaks of taking care of the stress due to dead load and that due to shrinkage by neutralizing their effects, as much as possible, by the method mentioned previously, that is, by building the concrete of the arch in sections and leaving key spaces between them to be filled in after the cement has set—in not less than 10 days, he states. His reference to neutralizing the dead load stresses is supposed to mean the stresses caused by the pressure line for dead load leaving the center line of the arch and thus causing a bending moment, as direct compressive stresses caused by the dead load, of course, cannot be neutralized in any way. All that is necessary to accomplish this is to design the arch so that the center line is the pressure line for the dead loads on the arch. When the dead load has been obtained, it is very easy to do this. As stated previously, this is probably as good a method as can be found, for a fixed arch, to neutralize the stresses due to setting, but is, certainly, very expensive; and it does not affect the stresses due to a change from the atmospheric temperature at which the arch was cast to the extreme variation either way.

In any of the Northern States the average temperature for June, July, and August is higher than 70°, and the winter temperature goes well below zero at frequent intervals. Therefore, in any open spandrel arch built in the Northern States during these three months, the drop in temperature will probably be—as a conservative estimate—at least 60 or 65 degrees. Mr. Maxwell has shown that, in Iowa, at least, the range will be much more than that.

If all arches could be built between March 15th and May 15th, or between September 15th and November 15th, this trouble would not occur, and a method of neutralizing the stresses due to setting, similar to Mr. Janni's and allowing a range of 40° each way from the normal, would probably insure the arch against cracks.

In Mr. Aylett's Fig. 8, an arch of I-section, there would probably be some danger of the flanges breaking off, as he suggests. These flanges should be at least twice as thick as shown by Fig. 8, as it is

Mr. Smith.

not practicable to approach the thinness of the steel beam flange with concrete. The proportions used in the Traver Hollow Bridge are shown on Fig. 10.

The writer, however, cannot see that there is much danger of these flanges being broken off, as the load of the arch is carried to the falsework as a distributed load across its lower surface. The paneling of the sides is of light construction and is not independent of the falsework, therefore it has to move with it, and, as the movement of the falsework is caused by a corresponding movement of the arch, the whole structure must, of necessity, move together.

It may be of interest to state that the writer has a letter from the contractor who built the Traver Hollow Bridge, stating that no difficulty was experienced in its construction.

The writer will admit that, if piers are to be built in a flowing stream, in which there are quantities of tree trunks with the boughs all nicely trimmed off a short distance from the trunk, so that they can catch on anything with which they come in contact, as shown in Mr. Aylett's Fig. 9, there might be danger of a quantity of drift collecting around the piers. However, he does not believe that there is much danger of an object, after being deflected by the cut-water, being drawn in again quickly enough to be caught by the down-stream leg of the pier. He can see no danger whatever of a tree trunk being deflected by the cut-water and then running in again with its butt between the legs of the pier, and then swinging around and hanging there. The cut-water throws the water away from the pier, and, on account of this obstruction, the water will be slightly higher as it passes, and hence the velocity will be increased. Any object deflected by the cut-water will be carried away from the pier slightly by this elevation of the water, instead of being drawn in.

In streams subject to heavy floods, where any obstruction of the channel would be serious, it is probable that wide piers would be out of the question, and undesirable, no matter what the economy would be in theory. The writer does not wish to be understood as claiming that the braced pier shown should be adopted in all cases, by any means, for he believes that the conditions at every important bridge should be investigated carefully. He thinks, however, that the braced pier is worthy of investigation when the design for a bridge is taken up.

Mr. Mensch is mistaken if he thinks that the writer claims, as a general thing, that the concrete in a three-hinged arch is about 50% less than in one that is fixed, and no statement to that effect was made in the paper. This happened to be a case where the comparison was unusually favorable to the three-hinged arch, as the proportion of rise to span is almost 1 to 6. The writer used this arch because he had designed it some years ago for the Rye Outlet Bridge,

and had all the dimensions on hand, and wished to compare a three-hinged arch with it. There are five arches in the Rye Outlet Bridge, and this is the center span taken for a single-arch bridge. Mr. Smith.

It is an interesting fact that though this comparison is so favorable for the three-hinged arch for a single span, when it is applied to the Rye Outlet Bridge there is very little difference in cost, not more than about 4%, if one does not take into account the steel reinforcement. The reason for this is that the bridge piers are so high and the superstructure so massive that the total cost of the arch concrete is only 13% of the cost of the bridge, and $13 \times 0.48 = 6.25\%$ without allowing for the cost of the hinges. Taking these into consideration, the difference is reduced to about 4 per cent.

In stating the conclusions in the paper the writer did not mean to claim that every individual design would necessarily agree with these conclusions, but that they were true in the average case. He thinks that the paper has brought out a valuable discussion on a subject which, heretofore, has not been treated at length, and is glad that the matter was brought up. He has not found anything in the discussion, however, to cause him to change his conclusions, but has been further strengthened in them.

STRESSES IN WEDGE-SHAPED REINFORCED CONCRETE BEAMS.

Discussion.*

By William Cain, M. Am. Soc. C. E.†

William Cain, M. Am. Soc. C. E. (by letter).—Mr. Janni makes a perplexing statement when he says: "cos. $(\alpha + \beta)$ is purely a symbol of a certain operation to be performed, and is not an actual value; its value is given by cos. α cos. β — sin. α sin. β". Perhaps this is a *"lapsus calami"*. All our textbooks state that the cosine of any angle, as $(\alpha + \beta)$, is an actual value and give tables of the actual values for various values of $(\alpha + \beta)$. Also, such values are often represented by certain lines on a unit circle, by aid of which the formula quoted is derived. By a consideration of such line values, it is at once seen that cos. $(\alpha + \beta)$ approaches indefinitely cos. β as α tends indefinitely toward zero, and the same result follows from using the development of cos. $(\alpha + \beta)$. Mr. Cain.

In fact, take the equation,

$$P\,Q = \frac{v\,\alpha}{\text{cos. } \beta - \alpha \text{ sin. } \beta},$$

which Mr. Janni gives. As he knows, α sin. β is an infinitesimal, and can be neglected in comparison with the finite quantity, cos. β, when connected with it with either a plus or minus sign. Thus, as α tends toward zero, without ever becoming zero, the value of $P\,Q$ approaches $\frac{v\,\alpha}{\text{cos. } \beta} = v\,\alpha \text{ sec. } \beta$, which is exactly the formula derived by the writer.

The writer cannot agree with Mr. Janni that the direction of the bending stress on the section, $N\,I$, varies in the manner shown in

* Continued from February, 1914, *Proceedings*.
† Author's closure.

Mr. Cain.

Fig. 9. It will presently be proved that the stress on the cross-section of an actual beam, varies continuously in amount and direction, so that no sudden change in direction of 90° at any point can occur.

This is true even at points of contact of wheel loads, for such loads are in reality distributed. So far as dams are concerned, the changes in the amount and direction of the principal stresses along horizontal sections have been determined, both theoretically and experimentally.

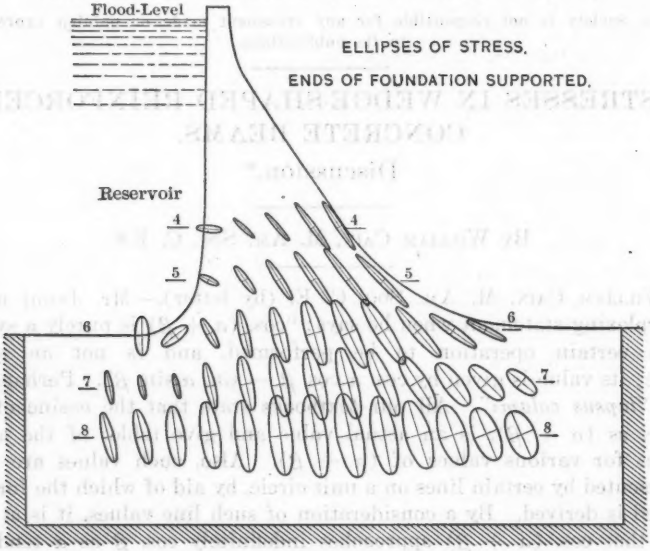

FIG. 13.

Reference has been made to the experiments on india rubber model dams by Messrs. Wilson and Gore. Fig. 13 is taken from their paper,* giving an account of these very interesting experiments. The unit stresses, in amount and direction, at numerous points in the dam, were determined from the distortions, and are represented by the ellipses of stress shown in the figure. The principal stresses, or those acting normally to their planes, are represented, in amount and direction, by the semi-axes of the ellipses. Of these, the maximum normal stresses are given by the semi-major axes and are those that specially interest us.

It will be observed that along any horizontal section, these unit principal stresses change gradually, in amount and direction. They are also observed to act parallel to the inclined down-stream face, very near that face. At the up-stream face, where the dam is subjected to

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907-08, Part II.

water pressure, the direction of the principal stress is nearly normal to that face, to counteract the large normal pressure of the water. Mr. Cain.

The same general results were first found theoretically by Mr. Ernest Prescot Hill,* for a dam with the up-stream face vertical, and later by the writer† for the up-stream face battered; both writers adopting the usual approximate trapezoid law for the distribution of the vertical components of stress on a horizontal section.

Fig. 14 represents the changes in direction of the greater principal stresses, as computed by the writer on a horizontal section of a dam, 200 ft. below the water level, the reservoir being full. For reservoir empty, the principal stress at the up-stream face would act parallel to that face.

Now, suppose that, for a dam of the same size and shape, but of less specific gravity, and capable of exerting tension, the resultant on the horizontal section passes much nearer the outer toe or beyond it; then a part of the section would be in tension, but the theory quoted shows that the continuity of stress, in amount and direction, would be preserved, and that there would be no abrupt changes in either, in going from the up-stream to the down-stream face. This continuity is preserved, as the center of pressure on the base moves indefinitely beyond the outer toe, and hence it is true at the limit, when the weight of the dam is neglected and the horizontal section is subjected to a pure bending stress and shear, due to the water pressure alone. Exactly the same reasoning applies to the toe, Fig. 1, supposed to be homogeneous, if we combine with the upward acting soil pressure, the friction between the toe and the earth on which it rests. The resultant of this frictional resistance, acting to the right, and the vertical soil resistance, meets the section, $I\ N$, or $I\ N$ produced; giving, as in the case of the dam, continuity of stress throughout the section. Now, let the friction force tend toward zero, then the point where the resultant meets $I\ N$ produced recedes indefinitely from I, but the continuity of stress, in amount and direction, is always preserved, and hence it is preserved at the limit, where the friction force is zero and there is only bending stress and vertical shear on the section, $I\ N$.

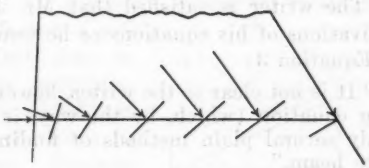

FIG. 14.

Thus, it has been rigorously proved that the bending stress in the toe, Fig. 1, whether or not soil friction is included, is inclined at the angle, β, to the horizontal at N, and this inclination is gradually and continuously lessened as we proceed down the section, $N\ I$, to I, where

*In a paper on "Stresses in Masonry Dams," *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, p. 134.

†*Transactions*, Am. Soc. C. E., Vol. LXIV, p. 208.

Mr. Cain.

it is zero. The same result, as to the continuity of stress, holds for any kind of a beam, subjected to any kind of distributed forces. This continuity of stress, in amount and direction, or the gradual change in both in passing along a joint, as proved above, seems to the writer to be axiomatic without any proof; but others may not think so, hence the proof.

It is difficult to see on what basis Mr. Janni assumes the discontinuity of 90° in the direction of the stress in Fig. 9. Presumably, the stresses act in the direction of the dotted lines. An obvious remark is, that if such directions were the true ones, then the arms of the corresponding stresses are less than those corresponding to the writer's hypothesis; so that even the writer's formulas would be on the danger side for the distribution of stress shown in Fig. 9; and the ordinary formulas, which Mr. Janni advocates, would be still farther on the danger side. There is thus an inconsistency which is fatal to Mr. Janni's contention.

The writer is satisfied that Mr. Janni has not read carefully the derivations of his equations or he would not have stated with reference to Equation 3:

"It is not clear to the writer, however, why the author gives a rather long equation (which, by the way, is not correct), when there are already several plain methods of finding that axis in a reinforced concrete beam."

The reference is to the neutral axis. It is hardly necessary to remark that if the "plain methods" are those pertaining to a prismatic beam (the only case ordinarily treated), they are entirely inapplicable to a wedge-shaped beam.

From overlooking this fact, Mr. Janni's Equation 23 is in error when β is not zero. The correct formula, assuming parallel compressive stresses, is given by Equation 15.

$$f_c = \frac{2\,M}{(b\,d)^2\,(k\,j)\,\cos.^2\beta}.$$

By the aid of Table 1, the values of f_c can be computed for various values of p and β, when b, d, and M are given.

In all the formulas, the value of β was supposed not to exceed about 45°, for reasons given, so that, when Mr. Janni, in Fig. 10, makes $\beta = 90°$, he is simply erecting a "man of straw" of his own in order to knock him down.

Further, in Fig. 10, to show a wedge-shaped beam, any dotted line must be extended to the left to represent the new upper surface, making the angle, β, with the horizontal. We are thus led to Fig. 1, where the resistance to bending along a vertical section is decreased, as compared with the case where $\beta = 0$, because the compressive stresses are now inclined to the horizontal and thus have shorter arms than for the case of the prismatic beam.

Mr. Cain.

The writer is pleased to know that Mr. Mensch thinks that the "assumption that the compressive forces are parallel to the compression face is certainly permissible in all cases where the percentage of reinforcement is low, say, less than 1 per cent." The next remark, that it "errs only slightly on the side of danger", presumably refers to the hypothesis of conservation of plane sections being adopted, as in the usual theory. Some experiments of A. M. Talbot, M. Am. Soc. C. E., seem to substantiate the hypothesis, those of Professor Schüle going the other way. For working loads, the hypothesis is universally used, as it is found to give safe results for reinforced prismatic beams, hence its adoption by the writer for the wedge-shaped beam, with the distinct proviso, however, that it was not to be used for large values of β.

Not only on this account, but principally because it was thought that the hypothesis of the compressive stresses, all acting parallel to the face in compression, departed too much from the truth for large angles, β was limited to about 45°, though, possibly, the limit might be extended to $\beta = 60°$, if the results are tempered with good judgment, which means a slightly increased factor of safety.

Mr. Mensch refers to the fact that in trusses with inclined compression members, the right section is used. It may be added that the stresses are taken parallel to the faces in metal beams with inclined flanges. Suppose a reinforced concrete T-beam, Fig. 15, with an inclined flange; would not a designer naturally take the compressive stresses in the flange as acting parallel to its surface? It seems absurd to take them as horizontal, particularly for the part of the flange on each side of the stem.

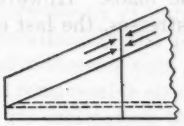

FIG. 15.

It is but one step now to the beam, Fig. 1, without a flange.

Mr. Mensch alludes to the fact that errors are sometimes made by using the factor, cos. β, in place of cos.^{2} β, in finding the compressive stresses. To emphasize this point, it should be remembered that A represents the area of a steel bar, taken at right angles to its axis, so that if f_s is the unit stress, the total stress in the bar is $f_s A$; but, considering a cylindrical "fiber" of the concrete, $N N'$, Fig. 2, the area of its section made by the plane, $I N$, is called Δa, so that the area of a section at right angles to the axis of the fiber is $(\Delta a \cos. \beta)$, and the stress on the fiber is thus, $f_c \cdot \Delta \alpha \cos. \beta$, f_c being the unit stress on the normal section.

For the fiber, $P P'$, Fig. 2, the stress is, similarly, $\frac{f_c}{kd_1} v \cdot \Delta a \cos. \beta$, where $O P = v$, and the sum of such stresses over the area, $O N$, is.

$$C = \frac{f_c}{kd_1} \cos. \beta \sum_0^{kd_1} (v \Delta a) = \frac{f_c}{kd_1} \cos. \beta \frac{1}{2} b (kd_1)^2,$$

Mr. Cain.

since $\sum_0^{kd_1} (v \Delta a)$ is the statical moment of the area under compression about the neutral axis.

Therefore $$C = \frac{1}{2} f_c \, b \, . \, kd_1 \cos. \beta,$$

and the moment of C about G is,

$$M_c = \frac{1}{2} f_c \, b \, . \, k d_1 \cos.^2 \beta \, . \, D \, G \ldots\ldots\ldots\ldots\ldots (8)$$

For the special case given by Fig. 7, G coincides with I, and $D \, G = jd$, on putting $d_1 = d$. Therefore,

$$M_c = \frac{1}{2} f_c \, (kj) \, bd^2 \cos.^2 \beta = \frac{1}{2} f_c \, (kj) b \, p'^2,$$

where $p' = d \cos. \beta =$ the perpendicular from I on $N \, N'$ produced.

Mr. Mensch states that he has advised calculating a wedge-shaped beam, Fig. 11, for a section, $R \, R$. It is not clear exactly what Mr. Mensch means by the statement, for there are mathematical difficulties in the way where the section, $R \, R$, is not parallel to the line of action of the loads. However, accepting the hypothesis of parallel compressive stresses, the last equation gives the precise result,

$$M_c = \frac{1}{2} f_c \, (k \, j) \, b \, . \, \overline{R \, R}^2$$

as $p' = R \, R$, of Fig. 11.

It is to be observed, however, that k and $j = 1 - \frac{1}{3} k$, must be determined for a section (say a vertical section in Fig. 11) through the lower R, parallel to the loads and not for the section, $R \, R$, as follows from the derivation of the formula.

Formula 16 is in the simplest possible form, and by aid of Fig. 6, the values of k can be read nearly to thousandths, and the computation easily effected. As a matter of fact, the steel percentage for the toes, heels, or counterforts of retaining walls, is nearly always very low, so that the steel is the determining factor. In any case, both M_s and M_c should be computed from Equations 14 and 16, for assumed values of f_s and f_c, and the least of the two equated to M, the moment of the external forces; or, if possible, the steel section should be revised, because under-reinforcement is in most cases preferable to over-reinforcement, as it leads to a more progressive, and not a sudden, failure, in case of excess loading.

Mr. Nishkian raises an interesting point in connection with Fig. 4 (referring to the case of the heel-slab with the fillet), that the vertical component of the stress in the inclined rods, for the width, b, should be subtracted from the total external shear to give the shear in the concrete in section, $I \, N$. It may be observed, in reinforced concrete beams, that the bending of the beam entails the interaction of

steel and concrete, without which the steel would be under no stress whatever. Thus the tensile stress in any bar, at a section, is necessarily accompanied with a reaction or an equal bond shearing stress in the concrete, along the entire surface of contact of the bar, to one side of the section. The steel elongates under stress, and this elongation is resisted by the concrete and the total reaction, for the length of bar to one side of the section—the total bond stress—is exactly equal to the tension in the bar. Thus the stress in the bar does not relieve the concrete of shear directly. Even where there are hair cracks on the tensile side of the beam, the full bond stress is exerted between the cracks, giving rise to ordinary shears, and these in turn to indirect tensions and compressions in the parts intact, which play an indispensable rôle in transmitting stresses and maintaining the integrity of the beam. Mr. Cain.

To deduce a formula for shear, only a part of the beam, such as is represented in Fig. 8, is considered. In an actual beam, as repeatedly pointed out, the compressive stresses are not all parallel to the face in compression, but their inclinations to the normal to $I\ N$ become less as the neutral axis is approached. In Fig. 8, the hypothesis of parallel compressive stresses is only used to establish approximately the point D, the point where the resultant, C, of the compressive stresses cuts $I\ N$. If C is now thought of as the resultant of the actual compressive stresses, having varying inclinations to $I\ N$, and calling β' its inclination to the normal to $I\ N$, the formulas which lead to Equation 17 are unchanged, provided we substitute β' for β. The angle does not appear in the final result. To realize further the conditions in an actual beam, tensile stresses in the concrete must be supposed between the neutral axis and the point where the hair cracks are experienced. Although, in the ordinary theory, such tensile stresses are ignored, yet it is seen, because they actually exist, that the section for maximum shear should strictly be taken at O, or at the neutral axis. Such ignored tensile stresses, though small, are nevertheless effective in changing the directions of the stresses in the concrete between the neutral axis and the point where cracks appear.

Formula 17 can be deduced in a different way from that given, which will introduce that interaction between the steel and concrete first alluded to. Let it be assumed that only shear of intensity, v, is exerted on a plane just below O, Fig. 8, that is, perpendicular to $I\ N$. Hence, adopting the previous notation pertaining to Fig. 8, the total shear on the plane is $v \cdot b \cdot dx$.

The bond stress exerted at the surface of contact of any bar, as $I\ I'$, throughout the length, $I\ I'$, is equal to the difference in the tensile stresses in the bar at I and I' and it acts in the direction, $I'\ I$. Hence the total bond stress exerted by all the bars is $(T' - T)$ in amount, and it acts in the opposite direction to T', if $T' > T$.

Mr. Cain.

If we call β_0 the angle made by the resultant, T (or T'), with the normal to $I\ N$, then $(T' - T)\ \cos.\ \beta_0 =$ the horizontal component of the total bond shearing stress exerted by all the bars, and this must equal the shearing stress, $v\ .\ b\ .\ dx$, exerted on the plane perpendicular to $I\ N$, just below O. Therefore,

$$v\ .\ b\ .\ dx = (T' - T)\ \cos.\ \beta_0.$$

Next, considering the free body, $N\ I\ I'\ N'$, held in equilibrium by the forces, V, V', C, C', T, T', acting as shown in Fig. 8, and taking moments about D,

$$(T' - T)\ \cos.\ \beta_0\ .\ \overline{D\ G} = V'\ .\ dx.$$

Eliminating $(T' - T)\ \cos.\ \beta_0$ between these two equations, dividing by dx, taking the limit as dx tends toward zero and V' tends toward V, and solving for v, we derive,

$$v = \frac{V}{b\ .\ \overline{D\ G}},$$

or Equation 17, which was first derived by a slightly different method.

At first sight, it might appear that the plane just below O, on which there is only shear, should be parallel to $T\ T'$, so that the shear on it should exactly equal the bond stress $(T' - T)$, which must be transmitted by ordinary shear to the neutral axis; but when we consider that along $O\ S$ (by the hypothesis), there is no bending stress, and hence no component of bending stress normal to $O\ S$, it follows that there can be only shear on $O\ S$, and hence a shear only of equal intensity on a plane normal to $I\ N$, say just below O, or between the neutral axis and the steel, if we ignore all tensile stresses in the concrete. The first equation above is thus justified. In the final equation for v, the whole external shear, V, appears, and there seems to be no justification for diminishing it by the component parallel to $I\ N$ of the pull in the rods.

A STUDY OF ECONOMIC CONDUIT LOCATION.

Discussion.*

By C. E. Hickok, Assoc. M. Am. Soc. C. E.†

Mr. Hickok.

C. E. Hickok, Assoc. M. Am. Soc. C. E. (by letter).—The writer wishes to confirm Mr. Hawgood's statement that the study of this particular conduit comparison was made under the latter's instruction. However, the diagram, Fig. 2, was originated and evolved by the writer.

The writer did not credit tunnels with any saving in seepage, as he was unable to ascertain even an approximate figure for this saving. He agrees with Mr. Hawgood that there would be a saving, but this depends so much on the nature of the tunnel material, which may vary from a pervious soil to hard rock, that there was a hesitancy as to what value to place thereon. There might even be an addition to the discharge of the conduit in the tunnel due to underground waters.

Mr. Hawgood's diagram, Fig. 3, is interesting and is certainly more compact than that of the writer.

In regard to Mr. Stein's remarks as to the thickness of the concrete in the different types of conduit, it should be stated that these drawings, Fig. 1, were not inserted in the paper to illustrate construction details, but simply for pictorial purposes. The drawings were not necessary, and possibly should have been omitted. The writer hopes that no engineer would attempt to construct, for instance, a concrete flume similar to that shown on Fig. 1, without reinforcement. In regard to the 3-in. thickness of concrete lining in the tunnel, the section was supposed to be in solid rock, and no concrete lining was intended to be shown above the springing line. This escaped the writer's notice, due to the fact that he was more interested in the real subject than in construction details.

MEASUREMENT OF THE FLOW OF STREAMS BY APPROVED FORMS OF WEIRS WITH NEW FORMULAS AND DIAGRAMS.

Discussion.*

BY MESSRS. CLARENCE S. JARVIS, AND GARDNER S. WILLIAMS.

CLARENCE S. JARVIS, ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Lyman's paper, and the discussions regarding stream measurement, are of unusual interest, and will be of much practical value, especially in the irrigated districts. Mr. Jarvis.

Mr. Lyman has admirably disposed of the stupendous task of correlating a mass of data collected under a wide range of conditions, with varying viscosity of the water due to temperature changes and to chemical elements held in solution or suspension, the slight variations in the intensity of the force of gravity, and the personal equations of the observers, as disturbing factors.

The graphical comparison, portrayed so clearly on Plate LXXXI, of actual discharges measured by eminent experimenters with the quantities derived by the use of the diagrams for sharp-crested rectangular weirs without end contractions, proves to be a very satisfactory test of the curves on Plate LXXX.

If a single type of weir were to be adopted, either the Cippoletti or the sharp-crested rectangular weir without end contractions would doubtless serve best in irrigation practice.

One advantage of the Cippoletti weir is illustrated by Robert S. Stockton, M. Am. Soc. C. E., in discussing the "Management of Irrigation Systems".† A portable sheet-steel Cippoletti weir, of 24-in. crest, is used by the ditch rider to measure the water supply in the various small laterals.

---

*Continued from February, 1914, *Proceedings*.

† *Engineering and Contracting*, January 28th, 1914.

Mr. Jarvis. In many irrigation districts where the slope of the country is slight, the writer has observed the need for a combination of measuring flume for current-meter gaugings and the approach to a suppressed weir. During the period of high water the canal or lateral is taxed to its capacity, and the obstruction required to give a free fall for such a stream over a weir is prohibitive. During this period current-meter gaugings are in order; and the rating curves for successive years need not change materially.

With the beginning of the low-water period, which, in the Great Basin region, is generally early in July, the duty of water is often increased two- or three-fold, and, with the reduced stream in the canal, it is possible to insert the weir crest in the measuring flume, thus providing a free overfall. The sediment does not interfere seriously after the high water has ceased; and the increased accuracy and reduced labor involved in the weir measurements recommend this method. Under these conditions the rectangular weir without end contractions provides the maximum width of crest and the minimum obstruction to the flow in the canal, and is much to be preferred.

In the writer's opinion, the data contained in Mr. Lyman's paper, and in the discussions, fill a long felt demand, and should wield a strong influence in the direction of higher duty for irrigation water, which will result from its careful distribution and judicious application on the irrigable land.

Mr. Williams. GARDNER S. WILLIAMS, M. AM. SOC. C. E. (by letter).—This paper brings to the front once more the measurement of water over weirs, and embodies the results arrived at by the author in a study of most of the data available in 1905, supplemented by some investigations of his own of more recent date. It is to be regretted that the hitherto unpublished data of experiments involved in this paper were not presented in such a concise form as to have warranted publication. In physical investigation, the one thing above all others that is valuable is a correct record of the experiments and their results. Opinions, theories, and conclusions are likely to change as time goes on, but physical facts remain physical facts, and may be as valuable 100 years hence as they are now, though the experimenter's conclusions may be long discarded.

A considerable part of the experimental work discussed in the paper was performed in the Hydraulic Laboratory of Cornell University under the writer's direction, and much of it under his personal supervision and with his participation, and the data have received careful study at his hands independently of the author's work.

Our basic knowledge of the quantity of water flowing over weirs rests on the experiments of Francis, Fteley and Stearns, and Bazin, all of whom experimented on weirs of different dimensions, and read the head of water at different places or by different devices. No volumetric

Mr. Williams.

measurements were made at Cornell prior to 1905, except in a few low head experiments wherein the inaccuracy of the volumetric measurement, on account of the large area and small rise in the measuring canal, was greater than that of any of the weir formulas could possibly have been. Since that date volumetric measurements have been made at Cornell over a weir 6 ft. long, and at the University of Utah, as described by the author. It is to be hoped that the data of the Cornell experiments may be presented in the discussion of this paper, as the volumetric determinations were probably more accurately made than in any other series of investigations by reason of the measuring basin being a vertical tube or stand-pipe 6 ft. in diameter and about 60 ft. high.

The builders of the Hydraulic Laboratory at Cornell made no provision for the reading of heads on the weirs contemplated. To cut chambers in the solid concrete of the walls and the rock adjoining it involved considerable expense, and when the first weir investigation was called for, that of the U. S. Board of Engineers on Deep Waterways, after some discussion, a device for communicating the head to glass tube gauges was adopted, consisting of a 1-in. galvanized-iron pipe, perforated with ¼-in. holes every 6 in. throughout its length, and placed transversely across the channel of approach, with the openings on the under side, and the pipe 8 in. above the bottom. Three such pipes were set for each weir, varying in distances from the base of the respective weirs. For this device there was then the unquestioned precedent of the similar apparatus at the Holyoke testing flume, which had been used there for many years, and is still. Before this series of experiments was completed, however, the possibility of an erroneous indication of head suggested itself, and, to test the matter, similar pipes were set in the floor of the timber flume leading to the lower weir, with the openings on the top and just flush with the bottom of the channel. The result was somewhat startling, for it was found that, for heads of about 4.50 ft., the original device was giving an indication about 0.30 ft. lower than that shown by the openings in the bottom of the channel. A series of simultaneous observations on the two devices was made, from which the former were corrected to the latter, and it was assumed that this latter device corresponded in its indication to those used by Francis, Fteley and Stearns, and Bazin. At the upper weir it was not so easy to get a series of openings flush with the bottom, as that would have necessitated cutting into the concrete, and after some study of existing data, the so-called standard tube-piezometer, described by the author on page 1577,* was adopted, and on the strength of the experience of Desmond FitzGerald, Past-President, Am. Soc. C. E., with a perforated pipe in a water main,† it was as-

* *Proceedings*, Am. Soc. C. E., for September, 1913.

† *Transactions*, Am. Soc. C. E., Vol. XXXV.

Mr. Williams.

sumed that the indication of this device corresponded to that of an orifice at the bottom of the side-wall similar to the one used by Bazin. With the correctness of this assumption, the writer was never entirely satisfied, but, during his connection with the Laboratory, from the conclusion of the first series of investigations, this device was used at the upper weir in all experiments and very carefully observed, all other devices being compared with it. During the earlier work the upper weir was taken as the standard, and the discharge over it was computed by Bazin's formula, using the indication of the standard tube for the head. In the spring of 1901 the lower standard weir was installed, and the head on it was usually read by the 13-ft., three-tube-piezometer, described by the author on page 1585.* The indication of this apparatus was never considered quite as reliable as that of the standard tube because of a greater likelihood of the presence of air in the pipe connecting it to its gauge. The lower sharp-edged weir was designed to be as nearly as possible a duplicate of the 19-ft., Farm Pond weir of Fteley and Stearns, it being 6.65 ft. high, or $\frac{1}{10}$ ft. higher than the Farm Pond weir, and 16 ft. long. During an extended series of experiments the head on this weir was read at a point 6 ft. up stream from the crest and just below its level, this coinciding with the practice of both Francis and Fteley and Stearns.

To those interested in the more precise measurement of water, the data obtained from the resulting use of different devices for reading head make the most valuable part of this paper, and are embodied in Tables A and B.

The first investigations, as to the effect on the apparent discharges, by different methods of reading the head on weirs, were made by the late James B. Francis, Past-President, Am. Soc. C. E., and are presented in "The Lowell Hydraulic Experiments".† These experiments are discussed by Messrs. Fteley and Stearns.‡

The next investigation of the subject of reading heads, so far as the writer has discovered, was that of Hiram F. Mills, Hon. M. Am. Soc. C. E.,§ which appeared to demonstrate that an opening in the wall of a channel, in order to transmit a pressure corresponding to the height of the surface of flowing water opposite, must be flush with the side, and the connecting pipe must be at right angles thereto.

The subject of indications of head, particularly as applied to closed channels, received further discussion, but without experimental evidence, in the paper on "Experiments Relating to Hydraulics of Fire Streams" by John R. Freeman, M. Am. Soc. C. E.‖

Mr. Williams.

In the paper on "Flow of Water in 48-In. Pipes" by Desmond FitzGerald, Past-President, Am. Soc. C. E.,* a statement appears covering the similarity of indication of a perforated pipe laid longitudinally on the bottom of a water main, and a series of circumferential orifices communicating to a chamber surrounding the pipe; and some further investigations along similar lines are presented in the paper on "Experiments on the Flow of Water in the Six-Foot Steel and Wood Pipe Line of the Pioneer Electric Power Company, at Ogden, Utah".† Beyond this, the effect of different methods of reading head does not appear to have attracted special notice until the writer called attention to it and presented experimental data bearing thereon, in the discussion of the paper, "On the Flow of Water over Dams," by the late George W. Rafter, M. Am. Soc. C. E.,‡ since which time nothing further has been presented in the publications of this Society, at least as applied to weirs, until the paper under discussion.

In these days, particularly in water-power work, where the competition between various manufacturers leads to the proposal of bonuses and forfeits, based on as small variations of discharge as one-tenth of 1%, exact knowledge of the influence of every departure from the standard of reference is of inestimable importance. In a recent test of water-power apparatus, a bonus of several thousands of dollars was apparently won, a considerable part of which was due to the introduction of irregular methods of observing the head on a weir, without a consideration of their influences.

Theoretically, what is desired in reading the head on a weir is to locate the elevation of the surface of the water, but, with channels of even very moderate widths, this will not be the same at all points across the stream, so that the measurement of it by even several tapes in a cross-section may not give an exact indication of the average head, and if it would, in no experimental investigation wherein the discharge of large weirs has been determined volumetrically, except those at the University of Utah, has such a process been used. The methods of transmitting the head through orifices in the side-walls or in plane surfaces parallel to them, as adopted by the leading investigators, is open to the criticism that the pressure thus transmitted is influenced by the velocity past the orifice to an extent that becomes decidedly appreciable at high heads. If, in order to avoid high heads, long weirs are used, the question then arises as to the applicability of an indication transmitted through the side-wall, to the establishment of the average head across a stream, say, 100 ft. wide. Bazin apparently conceived that the head should be transmitted from a location where the velocity would be the lowest possible, and hence selected a point well up stream from the pressure angle and at the bottom of the

* *Transactions*, Am. Soc. C. E., Vol. XXXV.
† *Transactions*, Am. Soc. C. E., Vol. XLIV.
‡ *Transactions*, Am. Soc. C. E., Vol. XLIV.

Mr. Williams.

side-wall. For long weirs it seems to be necessary to supplement this orifice by openings in the bottom of the channel at frequent intervals across it, and perhaps the most satisfactory device is a chamber extending across the bottom of the channel and communicating with it through medium-sized orifices at frequent intervals. Although it may be assumed that the indication of head transmitted through such a device cannot be very different, for short weirs, from that used by Bazin, it is nevertheless quite certain that it will not exactly coincide.

Different forms of transverse and longitudinal pipes, variously perforated, are frequently used, but both devices, if outside the pressure angle, are sure to read lower than an orifice in the wall near Bazin's location, on account of the reduction of pressure due to increase of velocity, as the location departs from the wall and bottom. In the experiments presented by the author, the standard tube, although intended, and originally supposed, to measure a head corresponding to that indicated by Bazin's device, fails to do so, and actually gives a lower one. The 11-ft., wall-piezometer coincides more nearly with a Bazin indication, but is still, in all probability, too low, as by the author's equation the Bazin reading is more than 5% higher than the 15-ft. tape.

Being taken in the open channel, the tape readings are far from satisfactory for fine work. At low heads, with smooth water, the tendency of the observer is to cut the surface too deeply, thus giving a low head, and, for high heads and rough water, the observer invariably reads too high. The same applies to observations with the point-gauge in running water. This accounts in part for the irregularity of the lines representing tape readings. Although, if the water is stilled, a skilled observer can do excellent work with a tape or any other form of point-gauge, the ordinary student, dealing with the rough water encountered at high heads, comes very far from getting ideally consistent results.

In order that the record may be complete to date, the writer presents the following data of comparisons of different methods of reading heads.

I.—At Cornell University Hydraulic Laboratory, 1899. Upper Standard Weir, 16 ft. long.

A = Standard tube, by double-tube gauge, as described by the author.

B = Upper transverse pipe, by double-tube gauge.

This was a 1-in. pipe perforated on the bottom with ¼-in. holes, 6 in. apart, extending across the canal parallel to the weir, 8 in. above the bottom and 27 ft. up stream from the 13.13-ft., high, standard weir.

C = Middle transverse pipe, by double-tube gauge.

This was in all respects similar to B, except that its location was 10 ft. up stream from the weir.

A and B and B and C were observed simultaneously on the same scale. Heads are from mean curves of the observations.

Heads.		
A	*B*	*C*
0.164 ft.	0.164 ft.	0.164 ft.
0.492 "	0.484 "	0.492 "
0.984 "	0.970 "	0.985 "
1.476 "	1.461 "	1.495 "
1.968 "	1.938 "	1.993 "
2.460 "	2.410 "	2.489 "
2.950 "	2.860 "	2.965 "

In these experiments it appears that *C* was probably within the pressure angle.

II.—At Cornell University Hydraulic Laboratory, 1899. Lower, Sharp-Edged Weir, 6.56 ft. long.

D = Flush pipe, by double-tube gauge.

This was a 1-in. pipe perforated on top with ¼-in. holes, 6 in. apart, and set with its top flush with the bottom of the flume, parallel to and 37 ft. up stream from the 5.2-ft., high, sharp-edged weir.

E = Upper transverse pipe, by double-tube gauge.

This was similar to *B* and 37 ft. up stream from the weir.

F = Middle transverse pipe, by double-tube gauge.

This was similar to *B* and 19 ft. up stream from the weir.

G = Middle flush pipe, by double-tube gauge.

This was similar to *D* and 19 ft. up stream from the weir.

D and *E*, *E* and *F*, and *D* and *G*, were observed simultaneously on the same scale. The heads for *D*, *E*, and *F* are from mean curves, those for *D* and *G* are from direct observations.

Heads.

Mr. Williams.

V.—At the University of Michigan, 1912. Special weir, 1.865 ft. long, with one end contraction of 1.08 ft. on side next orifices and gauge-reading devices. Weir, 11.46 ft. high.

M = Francis orifice, by hook-gauge.

This was ¼-in. in diameter, flush with side-wall, 6 ft. up stream from, and 0.34 ft. below, the level of the crest, connected by ¾-in. pipe to a gauge chamber 15 in. square.

N = Bazin orifice, by hook-gauge.

This was 4-in. in diameter, 7.32 ft. up stream from the weir, with its center 0.4 ft. above the bottom of the channel, connected by 4-in. pipe to a gauge chamber 15 in. square.

P = Point-gauge, its contact with the water surface observed electrically by the flash of a lamp.

This was situated in a 10 by 12-in. rectangular box of 2-in. plank attached to the side-wall above the Bazin orifice; the bottom of the box was fully open and 0.79 ft. above the level of the crest, and its down-stream face was 7.47 ft. up stream from the weir. The point was located 7.82 ft. from the weir, and 0.25 ft. from the wall side of the box.

The reading of the several gauges, corresponding to the crest of the weir, was determined both by wye-leveling and by water levels from a hook-gauge attached to the weir crest.

For M and N the crest reading by the water level was 0.005 ft. higher than by the wye-level, and for P, 0.011 ft. higher. This indicates that the determination of crest readings by wye-leveling results in slightly too high a head being used for the discharges. Similar results were obtained at the Holyoke testing flumes.

The heads observed were:

M	N	P
1.1551 ft.	1.1623 ft.	1.1758 ft.
1.3575 "	1.3883 "	1.3918 "
....	1.4572 "	1.4602 "
1.4386 "	1.4435 "	1.4456 "

It is to be noted that, on account of the small size of the opening for M, the water rose very slowly in the gauge tank, and the low reading of the second, as well as the relatively high reading of the fourth, observation may be partly due to that cause. The comparisons of N and P are believed to be very accurate.

As to the comparisons in the author's Tables A and B, it may be said that at the lower weir those of the Francis, float, and bottom piezometers, when more than one was used, being read by the same observer on the same scale of a double-tube gauge, should have been,

Mr. Williams.

and in all probability were, very carefully observed, and errors in one would be duplicated in the other.

The same is true as to comparisons at the upper weir between the 6-ft. longitudinal and 6-ft. wall, the 6-ft. longitudinal, the 11-ft. wall, the 2-ft. wall, and the crest piezometers which were observed in pairs on double-tube gauges, and the connections shifted so that the 6-ft. wall and 6-ft. longitudinal were observed with each other, and one of these two with all the others.

Tape and point-gauge readings, the standard tube, Bazin hook, and the longitudinal piezometers at the lower weir were necessarily read by different observers, and their differences involve a personal equation as well as possible inaccuracies in establishing the zeros or crest readings of the scale. The greatest care was taken in observations on the standard tube and the Bazin hook, and the work was very well done on those instruments and may be safely accepted. As to the tapes and the other apparatus, the writer does not feel quite so confident.

Table 0 consists of a series of coefficients to apply to the discharge of broad-crested and irregular weirs of a height of 11.25 ft. to give the discharge of weirs of other heights. This table is based on the effect of changing heights of sharp-crested weirs. Although the data used by the author seem to be the best we have, it is, nevertheless, to be remembered that the effect of a change of height on a broad-crested weir may be less than on a sharp edge, and hence the changes indicated by Table 0 may be too great. In other words, it seems probable that for flat-crest weirs higher than 11.25 ft., the discharge may be greater than that obtained in Table 0, and for similar weirs of less height than 11.25 ft., the discharge may be less than that indicated by the table, both by a small amount.

The evidence of Plate LXXXI, that all sharp-edge weir experiments fall substantially within 3% of a mean curve, is certainly valuable.

The curves shown on Plates LXXXIV and LXXXV are to be considered as approximate near the points where the lines deflect. There are conditions under which abrupt changes of condition arise in the discharge of weirs, but certainly nothing of the sort should appear in the standard weir at the points of deflection of its lines on these plates. More numerous experiments in the region of the deflections would show a gradual, not a sudden, change in the direction of the line.

In discussing the indication of the Francis orifice at the Lower Cornell Weir, on page 1548,* the author calls attention to apparently erratic readings, and offers as an explanation the possibility of an oblique current. This orifice was ¼-in. in diameter and near the center

Proceedings, Am. Soc. C. E., for September, 1913.

Mr. Williams.

of a smooth brass plate, 12 in. long and 6 in. wide, set flush with the timber forming the side of the canal. The likelihood of a current causing the discrepancy is remote, but a much more probable explanation is that the zero of the gauge was very close to the floor, and the observer had to lie in a very cramped position to observe low heads. All readings of the scale below a head of 1 ft. are likely to be low by a small amount, including the determination of the zero, on account of the observer not getting his eye on a level with the water in the glass. The effect of this at low heads would be to give a reading ranging between 0.004 and 0.002 ft. in error, which might be either high or low depending on the relative care with which the crest reading and low-head observations were made. From Plate XCIII it would appear that the low readings were high, which means that the zero was more accurate than the low-head readings.

The author's comparison of these indications by the approximate straight lines is open to some criticism, as the deviation of the line at some points from the true locus may be greater than that of the observations it is intended to harmonize.

On page 1579* attention is called to a note in the Laboratory Record, that the 6-ft. tape at the upper weir was below the beginning of the surface slope, and, therefore, was reading low. The statement is correct, and all the 6-ft. piezometers were similarly affected, and the fact stated, that the standard tube, 26 ft. up stream from the weir, was giving a lower reading than these, is to be explained by the relatively higher velocity past its orifices than past those near the wall. The reduction of pressure due to velocity past openings was imperfectly appreciated by the writer until experiments in a closed pipe showed that the pressure indicated by an orifice in a surface parallel to the axis decreased from the walls to the center when water was flowing.

In the writer's reduction of the experiments at Cornell, the results of which appear in the volume of Hydraulic Tables, of which he is a joint author,† the various discharge curves were compared with each other, with the sidelight of his personal knowledge of the peculiarities and characteristics of the several observers and apparatus involved. No attempt was made to establish the actual discharge in any case, but only to establish a ratio by which the discharge of a similarly dimensioned sharp-edged weir should be multiplied to give the discharge of the irregular weir. For himself, it involves less labor and conduces to accuracy to take the discharge of a sharp-edged weir from a reliable table and increase it by a known percentage than to compute the discharge *de novo* by using a special coefficient. If others prefer different methods, he has no objection, always bearing

* *Proceedings*, Am. Soc. C. E., for September, 1913.

† "Hydraulic Tables", Williams and Hazen, John Wiley & Sons, New York City.

Mr. Williams.

in mind, however, that the base discharge of the sharp-edged weir may be somewhat in doubt for cases beyond the range of experiment.

To the preparation of this paper the author has devoted a great amount of time and labor, a fact which no one more fully appreciates than the writer. He has assembled and presented in new form much valuable information, and for this is entitled to the thanks of all interested in the subject.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

Discussion.*

BY MESSRS. V. H. HEWES AND LAZARUS WHITE.

Mr. Hewes.

V. H. HEWES, M. AM. SOC. C. E.—The speaker would be glad if some member of the Board of Water Supply, who is familiar with the grouting work used in the siphons on the line of the Catskill Water Supply for New York City to check the excessive inflow of water during construction, would describe the method used in that work.

The speaker was granted the privilege of visiting the inverted siphon under the Hudson River where a heavy inflow was encountered, which threatened to drown out the pumps, although extra pumping facilities had been provided to care for such an emergency. A bulkhead was placed in the drift near the heading; pipes were introduced through the bulkhead, and grout was pumped through them, thus effectually reducing the inflow. After the bulkhead was removed and the work of drifting was continued, it was found that the cement had filled the rock seams both laterally and longitudinally. A sample of porous rock was shown which had been taken from another siphon on the line, where the grouting method was used to check the inflow. This sample seemed to be thoroughly impregnated with cement.

A description of the method used to relieve the water pressure on the outside of the concrete lining until the concrete had thoroughly set at points where there were small seams in the rock walls, and the subsequent grouting of these seams, would be exceedingly interesting.

Mr. White.

LAZARUS WHITE, ASSOC. M. AM. SOC. C. E.—It is interesting to compare the results at the Estacada Dam with those obtained on the Catskill Aqueduct. The Ashokan and Kensico Dams have very deep concrete cut-offs. Some grouting was done below these cut-offs, but only

* Continued from March, 1914, *Proceedings*.

Mr. White. as a secondary matter. In the sinking of the shafts there was considerable grouting, which afforded a good opportunity to see what it would do, because, in sinking a shaft, the portion grouted is subsequently excavated. The grouting of tunnels during driving also gives very definite information. The grouting work on the Catskill Aqueduct has been going on for 5 or 6 years, and has been watched for this entire period, so that observing engineers have come to some conclusions as to its results. These conclusions are remarkably similar to those expressed in this paper, which is exceptionally instructive.

The lack of success of a portion of the Estacada grouting is frankly admitted. It seems that in the last few years grouting has been made a sort of fetish; that is, people have been expecting too much from it. At best it is an uncertain proposition, and should be secondary to the customary work. The same applies to the excavation of tunnels. More water is cut off by the concrete lining than by the grouting. Grouting at times is wonderfully successful, but the conditions then are rather favorable; where the rock is hard, with definite splits and channels, the grout can be forced into it readily, but where it resembles the volcanic rock described by Mr. Rands the grout cannot be forced in thoroughly, but takes its own channels. It may run a long way from the part to be grouted, and on excavating this part, very little of it will be found. No one knows where it went—all that is known is that one has paid for it. At some shafts on the Catskill Aqueduct holes have been repeatedly grouted, and when the excavation was extended through the grouted zone the grout could hardly be seen—the same being even more true of grouted tunnels.

As a general proposition, the grout goes into places which the engineer has good reason to know exist, that is, into definite cracks or openings. At some shafts grouting has been very successful, but as already mentioned, the conditions there were favorable. Where unfavorable conditions were found, for instance, resembling those at the Estacada, grouting was not very effective. Judging by experience on the Catskill Aqueduct, the conclusions of this paper are entirely sound.

Grout always seems to obtain some set, but if it is forced into a place where there is water under pressure, and if the water is circulating, it will carry the grout out of the seams before it has a chance to set. Grout has been chased over tunnel arches, up and down, for hundreds of feet. Before the grout can set, it may be forced out, and pipes and seams which were thoroughly grouted may become empty, but if the grout is kept in place long enough, it will set no matter how much water is put in. This seems to be the speaker's experience.

AN INVESTIGATION OF SAND-CLAY MIXTURES FOR ROAD SURFACING.

Discussion.*

BY MESSRS. E. W. JAMES, ARTHUR H. BLANCHARD, AND SPENCER J. STEWART.

Mr. James.

E. W. JAMES, ASSOC. M. AM. SOC. C. E. (by letter).—The author has been particularly fortunate in his studies of sand-clay mixtures for road surfacing, in that his investigations have been made at the best point in all North America for such a purpose. The region especially concerned in the sand-clay type of construction is the Coastal Plain between the Upper Piedmont and Tidewater. According to State lines, therefore, Georgia, and especially North Georgia, is in the center of the sand-clay territory. The best natural mixtures are probably found wherever the Orangeburg sands of the Lafayette formation are prevalent or common. Having confined his investigations to these conditions, the author's conclusions are doubtless stated a little more strongly than they would have been had his experience or studies covered a wider territory. It is safe to state that sand-clay roads can be built in few sections of the United States in such a way as to give as great a degree of service as in Clarke or Elbert Counties, Georgia.

For several years the writer has had a wide experience in sand-clay work throughout all the Coastal Plain from Virginia to Southern Texas, and recognizes the importance of this type of construction. For a large section of the Southeastern States it is the only possible type of improved road for a large mileage of the country highways. The importation of stone is prohibitive because of excessive cost; shell is too friable and soft; brick, even on a natural sand foundation, is too expensive; and concrete is practically out of the question because of the cost of both sand and aggregate.

* This discussion (of the paper by John C. Koch, Assoc. M. Am. Soc. C. E., published in February, 1914, *Proceedings*, and presented at the meeting of March 4th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. James.

For many counties in the Southern States, therefore, the sand-clay road is the only improved type within the means of the locality, and the only one economically warranted by the conditions of traffic at the present time and probably for many years to come. In many sections, especially in the Tidewater and Coast counties the natural soils are prevailingly sandy. It is difficult to find good clays. The sand beds are as bad or worse than the clay mud of the uplands, and, moreover, they are bad, not only in winter, but all the year round. For this reason the sand-clay road is especially valuable in these sections. The natural soil is well drained, and the latitude precludes any lasting or great degree of frost. The question in these regions is not commonly to select materials that will produce a sand-clay of certain stability, but to use the materials at hand so skilfully as to produce alleviation of the almost intolerable conditions presented by the sandy roads.

In the counties along the coast, and usually for about 100 miles inland, the sands are fine and often floury; all clay, except occasional small pockets of white or gray pipe-clay, or a mottled red and gray variety, carries a large percentage of this fine sand. Consequently, the field methods of testing the clays described by the author would, in the writer's experience, result in rejecting a majority of those locally available, and of discarding all but the rarest deposits of sand.

The author's conclusions, however, are recognized as well founded, especially in regard to the value of coarse sand.

For sand-clay mixtures, the writer has frequently used a most simple field test, which has served his purpose well. The sources of material are located and selection is made, depending usually on the length of haul and the depth of the deposits beneath the surface. The immediate problem is to determine the best mixture of the materials selected.

Typical samples are taken of both sand and clay. Mixtures are made, ranging from 1 part sand to 3 parts clay, up to 3 parts sand to 1 part clay, or sometimes beyond these limits, if the materials appear to warrant it. These mixtures should be made to vary by one-half of 1 part, 1:3, 1:2½, 1:2, etc., 1½:1, 2:1, 2½:1, etc., and should be worked up with water into putty-like masses.

From each test, mix a small sample of from 1 to 2 cu. in., cut out with a small measure. The writer has found a small medicine glass, or even a large brass thimble, handy. It is only essential to get equal samples from each test mix. These samples are then rolled between the palms of the hands into reasonably true spheres and placed in the sun to dry. Some designating marks may be scratched on them. When thoroughly baked, they are placed in a circle in a flat pan or dish, and enough water is poured in the pan to cover them, care being taken not to pour the water on the samples.

Slaking will begin at once. The lapse of time found by Mr. Koch with his compressed specimens is not found at this stage. The slaking, however, will proceed at different rates. The sandy specimens will break down first, those with excessive clay will disintegrate second in order, and those having about the proper proportions will act more slowly. Usually, there will be one or two that determine the proper proportions of the materials, and, in the writer's experience, these will usually lie together in the series of test mixtures. Mr. James.

A supplementary test of some value can also be made on the dry spheres. Lightly rubbed with the thumb, those having too much sand will break down rapidly. Those having too much clay will soon begin to "dust" away, while those having the most stable mixtures will assume a slightly glazed effect under the light rubbing, due to the moisture and oil of the skin. These two tests will not give the same results. The dry test will indicate a mixture richer in clay as the better one, and the wet test will indicate a sandier mixture. The sample indicated as satisfactory under the wet test that lies between the other two will prove best in service.

These extremely simple tests do not determine the sand or clay content of the mixture, for the clay selected almost always contains considerable sand, and this, in most cases, contains silt or clay. The tests serve, however, to fix the actual values in the mixture of the pit run, as represented by the samples.

ARTHUR H. BLANCHARD, M. AM. SOC. C. E.—The speaker's discussion will be limited to calling attention to certain features of the construction of sand-clay roads which it is believed the author should include in his very valuable contribution to the literature on this subject. Mr. Blanchard.

The author states that the first cost averages $500 and the annual cost of maintenance is $5 per mile; and then emphasizes the fact, agreed with by the speaker, that there is a place for the sand-clay road. Very little information, however, is given with reference to local conditions. As the fundamental principle of sound practice is to use that type of road or pavement which is economical and suitable for a given set of conditions, it would be of great value to American engineers to have at hand especially more detailed knowledge relative to the traffic on the various types of roads referred to in the paper.

Another part of the paper which it is believed could be advantageously amplified is that relative to the effect of different percentages of sand-clay mixtures retained on the 10-mesh sieve, when such mixtures are used under various climatic and traffic conditions.

There are many highway engineers who, without doubt, will disagree with the author in dividing gravel and sand on the basis of material retained on or passing the 10-mesh sieve. The speaker believes that the 4-mesh sieve is rapidly being adopted as the basis of division between these materials.

Mr. Stewart.

SPENCER J. STEWART, ASSOC. M. AM. SOC. C. E.—The speaker has read this paper with great interest. From it it is evident that the clay-bearing materials are being given proper economic consideration in the highway development of the South. In New York State, however, clay is a material which, according to many highway engineers, possesses little or no value, but, on the contrary, contributes characteristics highly detrimental to proper highway construction.

Specifications prepared by highway commissioners, especially those of the State of New York, have insisted that the foundation course shall be filled with screenings, gravel, or sand, and have invariably ruled against a filler which would be classified as clay. From the speaker's experience, covering responsible charge of the construction of more than 300 miles of highways, at a total cost of $4 000 000, he has been led to believe that a clay-bearing material, if applied as a filler when dry, makes a foundation as stable, and less likely to disintegrate, than a filler of sand or the screenings of a non-cementitious stone.

It is common knowledge that clay may be used to advantage in binding the top course of macadam roads in cases where the dust from the crushed stone possesses no cementitious quality.

Perhaps it is not inappropriate, and may prove interesting, to call attention to the results obtained from the use of the sand-clay-bearing gravels of the Hudson River as a material for successful road construction. What is true of the cementitious gravel of the Hudson would be true of similar deposits in other parts of the country, but it should not be presumed that every gravel bank necessarily contains the characteristics of a cementitious gravel.

This material has been used for years on the Parkway Systems of Greater New York, originally as a water-bound material and, more recently, covered with hot oil. The roadways proved very satisfactory until the advent of the motor bus, which unusual traffic they could not withstand, nor was it ever intended that they should.

This same material has been used on the sandy soil of Long Island with excellent results, in spite of the crude method, or rather lack of method, used in the construction of some of the highways. Frequently, it was dumped on the sandy road, spread carelessly, and left for the traffic to compact into a smooth surface. In spite of this, however, it soon ironed out and made a most excellent road covering, considering the time and money spent on construction. On the other hand, under the direction of the New York State Highways Commission, roads of the highest type have been built of this material by the so-called water-bound method and the application of hot oil, proper care being exercised as to rolling and puddling.

With respect to roads of this latter class, the speaker wishes to call attention to one partial failure, point out the causes, and perhaps draw a lesson from the experience.

Mr. Stewart.

Hot oil had been applied during the late fall, and properly covered, but, in the following spring, the heat of the sun caused the oil to bleed and adhere to the iron tires of slow-moving vehicles, which drew up part of the top course and deposited it a few feet ahead. This resulted in alternate holes and mounds, and caused a very uneven surface which gradually became more pronounced as the holes became larger through wear. As soon as the first indication of bleeding occurred, the surface should have been covered with sand to prevent this unfortunate condition. One enterprising citizen did apply this remedy in front of his own property, with the result that the top surface is as good to-day as it was at the time of the completion of the road.

Hot oil treatment on water-bound roads, whether of stone or gravel, must have a certain amount of immediate attention during the period when the oil is susceptible to bleeding. Such attention simply means the application of blotting material.

As a foundation course on sandy soils, cementitious gravel has proved an unqualified success, at least in the speaker's experience, for he has known of no failures. Failures do not mean that a stretch of 50 ft. in 10 miles might not prove unsatisfactory; that might happen with any foundation, due to causes which could not be guarded against at the time by the construction engineer. The larger the mineral aggregate, the better the foundation, if just sufficient sand and clay are used to fill the interstices. If a mixing-method top is to be placed, the speaker would advise that the foundation course be thoroughly puddled and dried before the top course is laid.

As a foundation course for country highways, it is believed that gravel containing fines of a cementitious nature is to be preferred to either broken stone or concrete.

First, it costs less. Incidentally, it might be of interest to know that practically all materials entering into the construction of roads on Long Island must be imported, whether it be crushed stone, Hudson River gravel, or so-called Long Island gravel. The latter exists only on the north shore of the Island in any quantity sufficient to be used economically for work of any moment, must be dredged, barged to Long Island City, there transferred to cars, and then hauled to its destination. Even then, this material should only be used in concrete construction.

Where materials have to be imported, it should be remembered that broken stone, even at the same cost at the point of destination, costs approximately one-third more than gravel, due to its consolidation of about 33% under the weight of the roller, and also to the necessity of adding from 25 to 30% of sand or screenings to fill the voids. On the other hand, gravel, when measured in bulk on barges or cars, will about equal the quantity rolled in place on the road, requiring no extra material for filling. Concrete requires about 80% of the

Mr. Stewart.

rolled quantity of stone and gravel, with the addition of 40% of sand, together with the cement, the quantity of which depends on the proportion of the mixture.

On the contrary, where the importation of road-making material is unnecessary, the use cementitious gravel saves the cost of crushing and the incidental expenses associated with such process.

Second, a proper gravel foundation possesses the resiliency which is generally recognized as necessary for a successful road, especially for country highways. Broken-stone foundations possess this characteristic in a less degree, and concrete is entirely lacking in it.

In the case of asphalt pavements, they are now designed to overcome the lack of resiliency of the concrete foundation by the use of an intermediate or cushion course between the concrete and the asphalt surface. In the same manner properly designed mixing-method pavements of small mineral aggregate when placed on concrete foundations, should be provided with this cushion course.

Where conditions of traffic require a pavement of considerable permanency, the mixing method may be used. The speaker designed a pavement consisting of a mixture of asphalt and gravel in the proportion of 1 cu. yd. of loose gravel to an average of 20 gal. of asphalt, the gravel containing not less than 10% of clay. The gravel was bank run, the largest particles of which were 2 in. in the longest dimension, containing sufficient fines to fill the voids partly. The bitumen was a fluxed natural asphalt with a penetration between 10 and 13 mm. when tested for 5 seconds at 77° Fahr., on a No. 2 needle weighing 10 grammes.

The gravel was heated in a mechanical revolving dryer with a temperature of more than 225° Fahr., after which the asphalt, heated to not less than 275° Fahr., was added; then the mixture was placed in a revolving mixer until thoroughly and completely coated with bitumen. The mixture, at not less than 225° Fahr., was spread on the prepared bottom course with shovels from dumping boards and raked to a uniform surface with hot rakes, after which it was rolled with a self-propelled roller weighing at least 10 tons, until it was thoroughly consolidated.

On some sections of this pavement there was placed ½ in. of gravel screenings containing not less than 10% of clay which was saturated with water and rolled thoroughly and continuously until a clay mortar had been obtained. This process filled all the surface interstices with a gritty and adhesive substance which made the road practically "non-skid". In a short time the traffic drove away all surplus screenings, leaving a mosaic surface.

A different method of treatment was applied to this form of pavement in the more thickly settled communities. After the mixture had been rolled, it was covered with a coat of hot oil as a seal coat,

this seal coat being applied in November. In the following spring, under the action of the sun, the road bled to some extent, and became so sticky in a few places that the oil adhered to wagon wheels, which pulled up some of the top course. This condition could have been avoided if the authorities in charge had covered the pavement with sand or gravel screenings as soon as it became apparent that the hot oil had a tendency to bleed. No material harm was done, however, as the continuous traffic carried sufficient sand and dirt on the pavement so that in a short time the stickiness of the oil had disappeared. Mr. Stewart.

Such treatment obviates the general complaint against the so-called stone-mixing method pavement where a greater quantity of asphalt is used and where the seal coat is of the same consistency as the asphalt binder in the top course proper. These objections arise from the hardness and slipperiness of the surface, which, during the greater portion of the year, make it undesirable for horse traffic because of the former characteristic and to motor traffic on account of the latter.

It is suggested that, where the hot oil is omitted at the time of the original construction, the mosaic surface be covered with a hot oil treatment of ½ gal. per sq. yd. during the following year. With the hot oil as a squeegee course, in place of the seal coat of the same consistency of the bitumen, the pavement proper gives a less hard and slippery surface, which is desirable on country highways.

The speaker's experience has convinced him that a large plant, costing from $5 000 to $8 000, is not necessary in order to construct this pavement successfully, and that equally good results can be obtained from the use of small mixers costing from $1 500 to $2 000.

This pavement without the oil treatment cost about 85 cents per sq. yd., and with an oil seal coat about 90 cents per sq. yd. for a pavement 2½ in. in depth. This cost compares favorably with similar figures for mixing-method pavements in other parts of New York State. The speaker quotes from a statement attributed to a superintendent of highways, of New York State, relative to costs of similar pavements of graded stone material, as follows:

1½ in., California asphalt	$1.20	per sq. yd.
2 in., Topeka	1.20	"
2 in., Warrenite	1.30	"
2 in., Bitulithic	1.60	"

The gravel used in this pavement cost approximately $2.35 per cu. yd., f. o. b. destination, but where material can be obtained near the site of the works, the cost of 85 cents per sq. yd. can be materially reduced.

From observations of mixing-method pavements laid in New York City and vicinity, with graded stone as a mineral aggregate, it is ventured that the percentage of disintegration is as great, if not greater, than in the bituminous gravel pavement laid during the same

Mr. Stewart.

period of time. In fact, after 1 year's wear, out of a total of 112 000 sq. yd., or 0.04 of 1%, less than 45 sq. yd. of this gravel mixing-method pavement had disintegrated.

The road which received the treatment of hot oil in a squeegee course was dug up in many places during the year following its completion for investigating purposes, and, where removed, the material thrown back retained its vitality to such an extent that the top course healed itself so that a casual observer could not discover where the pavement had been disturbed.

In designing a country highway, not only the original outlay, but the cost and ease of maintenance should be given proper consideration. Those who have had experience in the upkeep of gravel roads realize the small expense necessary to retain them in their original condition. Where slight depressions occur from time to time, all that is necessary is to place a sufficient quantity of gravel in these depressions and allow the traffic to consolidate it. In cases where the road has become pitted to such an extent that it requires more extensive treatment, it can be scarified, harrowed, re-rolled, and puddled, and, with the addition of a small quantity of material, can be made as good as the original at a comparatively slight cost, due to the presence of the clay-binding material. This treatment cannot be successfully consummated in broken-stone roads, for as soon as the bond of an old stone macadam road is broken, the material is usually worthless. These peculiarities of the two materials result in a very pronounced saving in the maintenance of gravel roads, as compared with that of broken-stone roads, whether or not they had been subjected to hot oil treatment. The ease of maintenance of the gravel, mixing-method pavement is sufficiently illustrated by the self-healing incident referred to.

The speaker is led to believe that gravel, sand, and clay have not been given the consideration they deserve by the highway engineers of the United States. In a section of the country which possesses clay and sand-bearing gravel, engineers can well afford to investigate its uses for road-making purposes, either as a foundation course, a water-bound top course with or without hot oil treatment, or a top course using the mixing method.

To conclude, the speaker cannot express himself more clearly, relative to the use of gravel, than by referring to the following statement:*

"A well built and well maintained gravel road is preferred by automobilists to macadam roads or even roads paved with more expensive materials. The gravel road is springy and resilient and gives good grip to the tires. It does not produce the jar that exists in riding over a paved road with an unyielding foundation."

This is also true of the man who uses his horse for either business or pleasure.

REPORT ON A SERIES OF TESTS ON CONCRETE COLUMNS REINFORCED WITH A SPIRAL OF STEEL.

Discussion.*

BY MESSRS. EDWARD GODFREY, AND A. W. BUEL.

EDWARD GODFREY, M. AM. SOC. C. E. (by letter).—This is a valuable series of tests. It is unfortunate that such information, and proper interpretation and digestion of the same, were not available before common practice in reinforced concrete design was crystallized into the deplorable shape that it has taken in all building codes and in the report of the Joint Committee on Concrete and Reinforced Concrete, as well as in the standard books on the subject. Mr. Godfrey.

"Some experiments then made on the ultimate strength of columns with longitudinal steel bars embedded in the concrete indicated that such reinforcement, unless hooped or banded at frequent intervals, could not be relied on to increase the strength of the column, and in some cases might even render its strength less."

It is gratifying to know that truths, the recognition of which the writer has been seeking since 1906, are beginning to dawn on the Profession. He predicted that it would take 10 years. It will probably take that before the Joint Committee and the authors of building codes recognize the truth. Books will follow some years later, and the rodded column will have eked out its murderous existence.

The writer has followed this subject pretty closely, and, so far as he is able to learn, no one but himself had condemned the rodded column until recently, when it was criticized severely at a meeting of an engineering society in Chicago. It is absolutely true, as the

* This discussion (of the paper by C. G. Wrentmore, M. Am. Soc. C. E., and Messrs. Hugh Brodie and C. O. Carey, published in February, 1914, *Proceedings*, and presented at the meeting of March 18th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Godfrey.

authors state, that years ago experiments indicated that longitudinal rods do not reinforce a column, but it is just as true that the very authorities who made these experiments and who discussed them in their books, endeavored to explain away the facts and to apologize for the particular specimens of concrete in the weakened so-called reinforced columns. These same authorities recommend the addition of from 15 to 39% of strength for every 1% of this weakening steel.

What are the facts to-day? Every building code allows rodded columns; practically all the standard books recommend them; the Joint Committee Report allows them; nearly every great wreck has had them, and has been the result of them.

The authors are wise to ignore rodded columns in their tests and investigation, for the rodded column has absolutely nothing to recommend it to any intelligent man, and there can be no rational incentive to make tests on them except for the purpose of demonstrating their unfitness for structures, the unfitness that an intelligent analysis of the column will demonstrate, entirely apart from tests. It is deplorable that, though the Profession has been in possession of this experimental demonstration for a number of years, the facts have been so perverted, and recommendations have been so utterly contrary to what they have shown, that standard methods of constructing columns are criminally bad.

The writer would put quite a different interpretation on the tests made by the authors from that given in their paper. Their comparison between the plain and the hooped column is unfair to the former. Not that the plain column has any right to consideration as a structural member, but such comparisons give the hooped column an apparent advantage over other structural members, in the matter of unit stress, which it does not possess.

In calculating the unit load at first sign of failure, they have taken only the area of the core for columns with hooping, whereas they take the full sectional area of the plain columns. The area of the core is about 10 sq. in. and that of the full section is about 13 sq. in. Making this approximate correction on all their columns having embedded coils, the writer has discovered the following remarkable facts: The average load at first sign of failure for the 24 plain columns is 2 250 lb. per sq. in.; the average load at first sign of failure for the 18 columns having less than 1% of hooping is 2 250 lb. per sq. in.; the average load at first sign of failure for the 28 columns having more than 1% of hooping is 2 230 lb. per sq. in.; and the corresponding average values for the ten highest in the foregoing groups are:

Plain columns, 3 057 lb. per sq. in.
Less than 1% hooping, 2 614 lb. per sq. in.
More than 1% hooping, 2 769 lb. per sq. in.

Mr. Godfrey.

If these facts teach anything at all, they blazon out the truth that hooping has no influence whatever on the first failure of a column, and it is the first failure that is really the ultimate failure. A column is useless after it begins to spall on the surface.

The data presented by the authors on the ultimate strength of these columns are only of academic interest. They are totally erratic, and simply represent the post-mortem strength of columns which have already failed. How long it may take a rattlesnake's tail to cease wagging after its head is crushed, has no bearing on the safety of the persons who were menaced by the live snake. The load-resisting power of a more or less disintegrated mass of concrete encircled by a steel spiral has no bearing on the design of a safe structure, if the first sign of failure is ignored. The authors might as well take one series of columns and label them "A" and use their full area in determining the unit load, and then take another set which have gone through some treatment or other and label them "B", and use only 80% of their area, and then say, when Columns "B" stood exactly the same load as Columns "A", that Columns "B" were 25% better than Columns "A", as to make the comparison that Table 3 shows on its face.

We have it on the authority of Ernest McCullough, M. Am. Soc. C. E., that in a large number of commercial designs he has never found one which excluded the outer shell in the strength of the column. The writer has persistently refused to have anything whatever to do with the checking of rodded column installations, or doubtless he would have discovered the same thing. There is no reason why investigators should omit the outer shell of a column, either in making comparisons or in discovering the strength of columns.

These tests demonstrate several things. One is that the closer the pitch of the spirals, in general, the greater the ultimate strength of the column. This could be reasoned out by analogy. A brick will stand more load per square inch flatwise than on end. A mortar joint is stronger the thinner it is made. A flat disk will stand much more load than a high cylinder of the same diameter. There is a limit, however, beyond which this added strength is of no use. It would be unsafe to have a column in a structure with the shell outside of the coil spalled off. Hence the "first sign of failure" is the function that must govern in safe design. This value, in these tests, runs from 1 400 lb. per sq. in. up, on the full area in compression, on the hooped columns, or 1 800 lb. on the core.

Now what factor of safety will the Pittsburgh Building Code give, for example, allowing as it does from 1 300 to 1 750 lb. per sq. in. of alleged safe load on columns, as shown by T. L. Condron, M. Am. Soc. C. E..* Other building codes are not quite as bad as that of

*Paper before the Western Society of Engineers, Feb. 9th, 1914; *Engineering News*, Feb. 19th, 1914; *Engineering Record*, Feb. 21st, 1914; *Engineering and Contracting*, Feb. 18th, 1914.

Mr. Godfrey.

Pittsburgh, but those of St. Louis and Minneapolis are close seconds. The gravel concrete common in Pittsburgh is not nearly so strong in cylinders as the limestone concrete used by the authors.

In a testing machine, a column might show a certain strength at first failure, and two or three times as much at ultimate failure, but, if it begins to fail in a building, the sway and eccentricities unavoidable in structures will doubtless mean its ultimate failure.

One of the purposes of a factor of safety is to cover imperfections. What would happen in this "safe" Pittsburgh column, if a workman should drop a wooden block into it accidentally, or if there should be a void, filled up later by a trowel full of mortar? Who would be responsible for the possible general wreck of the building, the workman, the designer, or the commercial interests who get up these building codes? Laboratory tests are more carefully made than actual construction, so that this should be taken into account.

These tests demonstrate that there is no definite relation between the percentage of steel reinforcement and even the ultimate strength of the core. This, together with the facts concerning the pitch of the coil, shows clearly, what the writer has for many years contended, that Considère's formula is wrong. That formula, and it is used in the newest building code, which is that of Pittsburgh, would add to the strength of a column having a given pitch by adding to the size of the wire in the pitch, a perfectly absurd proposition, as the wire might already be strong enough to stand the crushing strength of the disk between two coils.

Another important fact brought out by the authors is that the ratio between the moduli of elasticity of steel and concrete is not more than 10. The value, 15, is very commonly used with a resultant degradation of design, where steel rods are considered in compression.

The authors state:

"That the shrinkage of the concrete, causing initial compression in the steel, might be the cause [of greater deformation in hooped columns] is untenable, because the concrete was immersed in water during the entire aging period."

It is presumed that the columns were dry when tested. Tests show that specimens shrink and swell by the mere process of drying and soaking them.

What the Profession needs is to ascertain the combination of spiral and longitudinal reinforcement for a column of given diameter, which will be consistent and properly balanced. This should then be adopted as a standard, and the value of a column should be based on the kind of concrete used, just as in beams or slabs. The longitudinal steel should be stiff enough and the coils should be close enough to hold these rods from buckling. The writer* advocated this in 1906 and worked out such a standard.

*In his book entitled "Concrete."

Mr. Godfrey.

The Profession is not in need of tests so badly as of proper interpretation of those already made. This is not said in disparagement of those made by the authors. They are of great value. What is sorely needed is complete revision of building codes, books, and of the Joint Committee Report. The present standards of reinforced concrete design are dangerous and outrageous.

Mr. Buel.

A. W. BUEL, M. AM. SOC. C. E.—It appears to the speaker that the programme for this series of tests was planned so that results or conclusions of much practical value or reliability could hardly be expected, at least none commensurate with the expenditure.

The slenderness ratio, about 6.75 for the concrete or 7.7 for the coil, was much too small to represent conditions in practice, and should classify the series with compression tests rather than with column tests.

The concrete mixture, 1:2:4, was too rich to use economically with spiral or hoop reinforcement, and the tests do not show the true value of such reinforcement, which is greater with lean concretes. Some indication of this is shown by a comparison of the short- and long-time tests of this series.

The section of the test columns was so small that the results will hardly be depended on as a basis for structural designing, in view of the fact that engineers already have reports of a considerable number of full-sized tests. Some 6 or 8 years ago, when very few reports of full-sized tests were available, such tests as these would have been received as a valuable contribution. A dozen full-sized column tests, carried out on a well-planned programme, would be a more valuable addition to the experimental data on the subject than several hundred tests on small model specimens having dimensions entirely out of proportion to those generally found in practice.

The pitch of the spirals varied from 0.25 to 0.75 in., in columns of the same group. This, and also the variations in age, make it impossible to compare fairly the results from one test column with those from another, to draw reliable conclusions, or, for practical purposes, to realize what the authors describe as the "Aim of the Tests".

The records of "first sign of failure", particularly for the short-time tests, do not agree with tests reported by other experimenters, where the envelope of concrete or cement outside of the spiral or hooping almost invariably began to show signs of failure as soon as the load reached or exceeded the ultimate load of a similar column without reinforcement. In other words, all previous tests have indicated that spiral or hoop reinforcement does not materially raise the point of first sign of failure. Mr. Godfrey has pointed out what seems to be an error in computing the intensity of stress at first sign of failure: that the area of cross-section enclosed by the spiral was used, whereas the area of the entire column, including the concrete outside of the spiral, should have been taken for this computation. For the determin-

Mr. Buel.

ation of the intensity at the ultimate load, the area enclosed by the spiral is correct, because at that time the outside envelope would have been destroyed.

In a number of cases the pitch of the spirals was somewhat higher than that recommended by Considère for maximum efficiency of hooping. This was confined mostly to columns with the smaller percentages of spiral reinforcement.

Most of the eight conclusions drawn by the authors from the results of this series of tests are in substantial agreement with those deduced from previous experiments, and can be considered as a confirmation of the latter.

Conclusion No. 2 gives a value for e, the ratio of the modulus of elasticity of the steel, E_s, to that of the concrete, E_c, which is remarkably low, considering what engineers have been accustomed to use and the results of previous experiments. The speaker would like to ask the authors whether the value of E_c, which they derive from the formula, $600\,000\ f_c \div s_2$, is the true value of E for concrete alone, and is it not possible that it was affected by the spiral reinforcement to some extent? Also, what was the value of E_c for the plain concrete columns without reinforcement? Is not the E_c computed by the authors' formula, the E for the column as a whole, rather than the E for the plain concrete?

Conclusion No. 5, that the spiral reinforcement materially raises the limit of the first sign of failure, will require further experimental demonstration to be fully convincing, in view of the considerable number of determinations which have shown different results.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE GAUGE OF RAILWAYS, WITH PARTICULAR REFERENCE TO THOSE OF SOUTHERN SOUTH AMERICA.

Discussion.*

By Messrs. Philip W. Henry and James J. Hill.

Philip W. Henry, M. Am. Soc. C. E.—This paper contains a great deal of valuable information, particularly for those interested in the construction and operation of railways in Latin-America, and the author is to be congratulated on the exhaustive and intelligent manner in which he has treated this important subject. Of special value is his emphasis on the distinction between a "narrow-gauge railway" and a "light railway", which are often used as synonymous terms, although, as the author points out, a "light railway" may be of any gauge. Mr. Henry.

The speaker agrees with Mr. Lavis that the difference in the construction cost between a narrow-gauge and a standard-gauge railway is generally exaggerated. In a country the traffic of which does not admit of the construction of an expensive railway, and where the prevailing gauge is 4 ft. 8½ in. or greater, the speaker believes that it is better to cut the construction cost by raising the maximum grade and curvature rather than by lessening the gauge of the railway. Though the author treats of railways chiefly in the southern part of South America, more particularly Argentina and Southern Brazil, both lying within the temperate zone, where conditions are quite similar to those in the Central Western States, and where traffic will follow railway construction almost as rapidly as it did in those States, it must be remembered that in tropical South America and in Central America traffic does not follow with the same rapidity, and, therefore, the type of railways for those countries may be quite different from that suitable to Argentina and Southern Brazil. Broadly speaking, it is safe to

*This discussion (of the paper by F. Lavis, M. Am. Soc. C. E., published in March, 1914, *Proceedings*, and presented at the meeting of April 1st, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Henry.

assume that in Central America, the West Indies, and in tropical South America, the gross earnings of a new railway for the first few years will not be much greater than operating expenses, let alone interest on the capital invested, and that the development of traffic will be very slow, unless the parties building the railway undertake at the same time to develop traffic. Even in a highly fertile tropical country, it is seldom that the natives, who are well satisfied with their existing life, will make any effort to develop traffic on any considerable scale. The development of tropical agricultural traffic in most cases demands both capital and skill. This applies particularly to the raising of bananas and sugar cane, two of the most profitable tropical products.

If the railway is built in the high altitudes of Peru or Bolivia, not susceptible of agricultural development, it is essential that mineral traffic be developed, which, again, requires large investment of capital. In some cases, the building of a railway may be followed by the investment, on the part of outside capitalists, in the agricultural or mineral resources of the region traversed by the railway; but, generally speaking, if the parties building the railway are also its operators, it is essential for best results that, at the same time they acquire the concession for building the railway, they should take steps for the development of traffic—a point which is generally overlooked. The Governments often recognize this slow development of traffic, either by guaranteeing the bonds of the railway or by paying a cash subsidy approximating, if not equalling, the cost of construction.

The speaker believes that the author has over-estimated, if anything, the additional cost of constructing a standard-gauge railway (4 ft. 8½-in.) over that of a meter-gauge, especially where he adds an extra cost for "Contingencies, Expenses of Promotion, and Interest during Construction," amounting in all to 15%, which, according to his figures, equals $249 per mile on roads of light earthwork and bridging, $430 per mile on roads of medium earthwork and bridging, and $1 359 per mile on roads of heavy earthwork and bridging. It appears to the speaker that this item of general expense is the same, regardless of the gauge of the railway. In other respects, the speaker believes that the author's estimates are, if anything, more than ample. The extra cost of standard-gauge, given by him in detail for the three classes of railways, neglecting the 15% for general items as above, is as shown in Table 28.

To confirm these figures, it is interesting to compare the actual cost of building a railway of light earthwork and bridging in Bolivia, from Viacha to Oruro, 127 miles in length, with which the speaker was connected in 1906-09. This railway was of meter-gauge, roadbed of 5 m., the average cross-section for the entire length showing excavation actually paid for, both in cuts and borrow-pits, amounting to an average depth of 3.7 ft. Assuming that the railway had been of standard-

gauge, instead of meter-gauge, it would have been necessary to handle $6\frac{1}{2}\%$ additional earthwork. It is assumed that the cost of bridges, trestles, and culverts, and of tracklaying and surfacing, would also have been increased by $6\frac{1}{2}\%$, certainly a liberal estimate. The ties, California redwood, costing about $2, delivered on the work, were 7 ft. in length, instead of 8 ft., if standard-gauge had been adopted, making an additional cost of $14\frac{2}{7}\%$ for ties. Table 29 shows the actual cost per mile of the different items affected—in the speaker's opinion—by the change in gauge, and the additional cost for each item in case standard-gauge had been adopted. Mr. Henry.

TABLE 28.

	Light earthwork and bridging.	Medium earthwork and bridging.	Heavy earthwork and bridging.
Earthwork	$310	$980	$5 010
Bridges	150	500	2 000
Culverts	150	300	1 000
Ties	770	770	770
Laying and surfacing	100	100	100
Yards and sidings	170	170	170
Cattle guards, fences, etc.	10	10	10
Total for construction	$1 660	$2 830	$9 060
Less saving in equipment	100	100	100
Net Total	$1 560	$2 730	$8 960

TABLE 29.

	Actual cost, meter-gauge.	Estimated additional cost, standard-gauge.	Total estimated cost, standard-gauge.
Grade	$4 200	$272	$4 472
Bridges, trestles and culverts	2 600	168	2 768
Tracklaying and surfacing	1 600	97	1 697
Ties	5 100	737	5 837
Total for these four items	$13 500	$1 274	$14 774

This shows an estimated additional cost of standard- over meter-gauge for a railway of light earthwork and bridging of $1 274, as compared with the author's estimate of $1 560, neglecting general expenses.

The question of gauge, except perhaps in Argentina and Southern Brazil, is not likely to arise on railways of medium or heavy earthwork and bridging, but it is more likely to arise on those railways built in districts of light traffic, where it is necessary to cut down the expense of construction to the lowest possible limit. As stated before, the speaker prefers to do this by building a railway of the gauge standard

Mr. Henry. to the district, high maximum grades and curvatures, say, 3½ or 4% and 25° curves, intelligent discrimination being used in the application of these maxima. By using the Shay or a similar type of locomotive, the maximum grade may be run up to 8 per cent. As one train each way per day—sometimes only two or three trains per week—will take care of all the traffic, it is evident that the cost of conducting transportation is a small item when compared with the cost of maintenance of way and with the interest on the cost of construction. Therefore, under such conditions of light initial traffic and slow development of traffic, the first cost of construction, with due regard to maintenance of way, should be the controlling factor. At first sight, this would indicate a narrow-gauge railway, which admittedly can be built at from $1 000 to $1 500 per mile lower cost than standard-gauge, the interest on which at 7% is from $70 to $105 per mile per year, quite an item for a railway the gross earnings of which may run from $1 000 to $1 500 per mile per year. Still, other considerations must be taken into account, such as gauge of connecting railways or of railways likely to be constructed. In Bolivia the gauge of the railway from Viacha to Oruro, 127 miles, was fixed at 1 m., as it was intended eventually to connect it with the Argentine Railway on the frontier, 425 miles distant, which is of meter-gauge, thus furnishing a through route from La Paz, the capital of Bolivia, to Buenos Aires. In Haiti and Santo Domingo, where the largest mileage of railways is of 42-in. gauge, that gauge will naturally be adopted for future railways in that island. In a country, however, where standard-gauge now prevails, or is likely to prevail, the building of a narrow-gauge railway is of doubtful expediency, and the speaker would prefer reducing the first cost by high maximum grade and curvature.

Mr. Hill. JAMES J. HILL, F. AM. SOC. C. E. (by letter).—In the development of much of the territory of the United States, the original cost of construction of the 4 ft. 8½-in. gauge was all that (and in many cases more than) the country could bear, though the writer has long felt that it is not certain but that, for very heavy traffic, a 5 ft. 6-in. gauge would have been better. The difference in the dead weight of the car would not be great, and the center of gravity would be nearer the rail.

DISCUSSION ON BITUMINOUS MATERIALS FOR ROAD CONSTRUCTION.*

By Clifford Richardson, M. Am. Soc. C. E.

Clifford Richardson, M. Am. Soc. C. E. (by letter).—This report rings the changes on a number of conclusions with which most experienced road builders are acquainted and with which they will agree. They can, probably, not be brought too often to the attention of those who are less well informed. In some directions, however, these conclusions will not be agreed to by all road builders of experience, nor will there be complete unanimity, as far as approval of some of the definitions proposed by the Committee is concerned. Mr. Richardson.

In discussing the mixing method the report states "Excessive sizes * * *, of the mineral particles should be avoided". It seems to the writer that this statement should be modified. The use of large-size stone, 2½ in., is not objectionable if the road crust is of sufficient thickness to permit it, and if the surface is well closed up with finer material, but it would be absurd to use such a stone in a 3-in. thickness, for instance. The size of the stone should be accommodated to the thickness of the road crust, but where large stone can be used, the surface shows greater stability with large-size particles than with small ones.

Under the same subject, the report says that "Mixing machines should be used, and hand-mixing methods should be avoided wherever practicable". The difficulty with the mixing process lies in the fact that most mechanical mixers will not handle large stone in a satisfactory manner, and that hand-mixing is necessary for such a purpose. In the writer's experience, some of the best roads with which he is acquainted have been constructed by hand-mixing processes, as, for

* Continued from February, 1914, *Proceedings*.

Mr. Richardson.

example, Western Avenue, in Gloucester, Mass., which was built by this process in 1909.

All road builders of experience will agree with the Committee's conclusion that the use of fine sand on top of bituminous concrete is open to grave objection, and that clean stone chips, or small gravel free from particles that will pass a ½-in. mesh screen, is preferable.

Among the Committee's conclusions in regard to the construction of road surfaces by the penetration method is one which states that "An important factor for successful results is the thorough compaction by rolling of the road metal before the spreading of the bituminous material". In the writer's experience, though this may be true where the bituminous binder is one which melts to a slightly viscous liquid and, in consequence, might not remain in place with the stone not thoroughly rolled, it is far from being so when the binding material consists of the more viscous and stable natural asphalts. Experience has shown that better results are obtained in using the natural asphalts for penetration purposes if the rock is merely spread, the road asphalt being applied thereto without rolling, followed by a course of smaller stone, and compaction after this application. The Committee is certainly right in stating that "the use of fine sand on top of the bituminous material is open to grave objections" and that clean stone chips are preferable. No one who has had extended experience in road construction could differ from these conclusions.

Not all engineers will agree with the Committee's suggested definition for an "aggregate", in so far as the statement goes that "the broken stone may be referred to as the aggregate and the sand, stone dust, or other fine material may be referred to as the binder". If such a definition were accepted a sheet-asphalt surface would contain no mineral aggregate.

The definition proposed by the Committee for bitumen is that adopted by the American Society for Testing Materials, as suggested by a Committee of that Society. At the meetings of that Committee and, before the Society, the writer raised very strong objections to the use of the word, bitumen, in a sense other than that of its etymological origin, and presented a Minority Report,* which, as the definition has again been proposed for presentation to the American Society of Civil Engineers, should, he thinks, be brought to the attention of the membership. It is, therefore, here reproduced:

"In the writer's opinion, the definitions presented are unsatisfactory, both in matter and form, and in one instance is quite contrary to the etymological significance of the word defined. The majority report defines bitumen as a 'mixture of native or pyrogenous hydrocarbons and their non-metallic derivatives, etc.' The Committee throws over all authorities that have heretofore ruled on the subject, and provides

* *Proceedings*, Am. Soc. for Testing Materials, Vol. XII, p. 75.

that by its arbitrary decision coal tar is a bitumen. It is stated by the Committee that it believes the definitions of the dictionaries and encyclopædias are unsatisfactory, and brushes aside the following definitions of our best known dictionaries and writers: Mr. Richardson.

"'Bitumen: The name given by Latin writers, especially by Pliny, to various forms of hydrocarbons now included under the names asphaltum, maltha and petroleum'. "Century Dictionary, Edw. S. Dana, Ph. D.

"'In modern scientific use, the generic name of certain mineral inflammable substances, native hydrocarbons more or less oxygenated, liquid, semi-liquid, and solid, including naphtha, petroleum, asphalt, etc.'
"New English Dictionary, Murray.

"'Any native mixture of hydrocarbons, oxygenated, as naphtha and especially asphalt'. "Standard Dictionary.

"'By extension, any one of the natural hydrocarbons, including the hard, solid, brittle varieties called asphalt, the semi-solid maltha and mineral tars, the oily petroleums, and even the light, volatile naphthas.'
"Webster's Dictionary.

"'This term includes a considerable number of inflammable mineral substances consisting mainly of hydrocarbons. They are of various consistence, from thin fluid to solid, but the solid bitumens are for the most part liquefiable at a moderate heat. The purest kind of fluid bitumen called naphtha, or rock oil, is a colorless liquid of specific gravity 0.7 to 0.84 and with a bituminous odor. It often occurs in nature with asphalt and other solid bitumens. Petroleum is a dark-colored fluid variety containing much naphtha. Maltha or mineral tar is a more viscid variety. The solid bitumens are asphalt (q. v.) mineral tallow or hatchetin; elastic bitumen, mineral caoutchouc or elaterite; ozokerite.' "Dictionary of Applied Chemistry, Thorpe.

"'A generic name for a variety of substances found in the earth, or exuding from it upon the surface, in the form of springs. The liquid varieties become inspissated by exposure and eventually harden into the solid form, which is asphaltum.'
"Appleton's American Cyclopædia.

"'Bitumen is the name used to denote a group of mineral substances, composed of different hydrocarbons, found widely diffused throughout the world in a variety of forms which grade from thin volatile liquids, to thick semi-fluids and solids, sometimes in a free or pure state, but more frequently intermixed with or saturating different kinds of inorganic matter.'
"From 'Highway Construction', by Austin T. Byrne.

"'The word bitumen may, therefore, be strictly defined as a general term that is used to designate a class of minerals as they occur in nature, that are soluble in chloroform and other neutral liquids.' "S. F. Peckham.

"'Any mixture of hydrocarbons and their derivatives of mineral occurrence whether solid, liquid or gaseous, which is soluble in chloroform or similar solvents.' "George W. Tillson.

Mr. Richardson.

"It seems to me that this is a most arbitrary procedure. If the definition in Thorpe's Dictionary of Applied Chemistry cannot be accepted as a satisfactory one for bitumen, the entire structure of chemical nomenclature might be overthrown.

"As a substitute for the definition proposed by the majority of the Committee, I would suggest the following:

"Bitumen is a material found in nature, consisting of a mixture of hydrocarbons and their derivatives, which may be a gas, liquid, a viscous liquid or maltha or a solid but, if solid, melting more or less readily on the application of heat and soluble in carbon disulphide or similar solvents.

"The definition of 'bituminous' is equally unsatisfactory from the writer's point of view, being defective in so far as it is based on the previous definition of bitumen. The writer would suggest the following:

"A material is said to be bituminous when it contains bitumen or material resembling bitumen, or if it yields bituminous material, or if it constitutes the source of bituminous material. Coal-tar is called a bituminous material from its resemblance physically to some of the denser forms of the native bitumen, although it contains no bitumen. Bituminous macadam is a road surface bound with bitumen or bituminous material."

To this Minority Report, four members of the Committee replied that the application of the term bitumen to coal-tar is sanctioned by Allen in his "Organic Analysis", Dr. David T. Day of the U. S. Geological Survey, Prévost Hubbard, Assoc. Am. Soc. C. E., of the Committee, in his publications, by the American Railway Engineering Association, in the "American Civil Engineers' Pocketbook," and in the Progress Report* of the Special Committee on Bituminous Materials for Road Construction, of the American Society of Civil Engineers, and that bitumen is used, in the sense adopted by the Society, in the specifications of such States as New York, Pennsylvania, Illinois, New Jersey, etc., and by many city authorities like George W. Tillson, M. Am. Soc. C. E.

On the other hand, such an authority as M. Paul le Gavrian, Assistant Secretary, International Association of Permanent Road Congresses in Paris, has stated in reply to an inquiry from the writer:

"I am of your opinion as regards the abuse of the word 'bitumen'. It should be used only to denote natural products and not the tars and their derivatives. I go even farther than you and wish that the term 'bitumen' might be reserved solely for materials containing natural bitumen."

Again, Colonel Crompton, Consulting Engineer of the Road Board of Great Britain, writes:

"You are right in supposing that I agree with you that coal-tar is certainly not bitumen."

* Presented to the Annual Meeting of the Society, on January 17th, 1912.

Mr. Richardson.

The subject is to be considered by the Engineering Standards Committee of Great Britain in conjunction with some of the American authorities, in consequence of a meeting held in London at the time of the recent International Road Congress. In view of what M. le Gavrian and Colonel Crompton think, it hardly seems to the writer that there can be any unanimous acceptance of the American definition for bitumen at the present time, and, this being the case, it would seem to be wise not to attempt, in view of the controversial nature of the matter, to force it on the engineering world, by a majority vote, which will probably chiefly be cast by individuals not directly interested in the subject, even if the majority is very large.

The subject is to be considered by the Engineering Standards Committee of Great Britain in conjunction with some of the American authorities, in consequence of a meeting held in London at the time of the recent International Road Congress. In view of what M. le Gavrian and Colonel Crompton think, it hardly seems to the writer that there can be any unanimous acceptance of the American definition for the time at the present time, and, this being the case, it would seem to be wise not to attempt, in view of the controversial nature of the matter, to force it on the engineering world by a majority vote, which will probably chiefly be cast by individuals not directly interested in the subject, even if the majority is very large.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

BY MESSRS. F. LAVIS, H. C. PHILLIPS, WILLIAM W. CREHORE, M. R. MALTBIE, HENRY FLOY, V. K. HENDRICKS, WILLIAM J. WILGUS, RICHARD T. DANA, R. S. MCCORMICK, RICHARD J. MCCARTY, A. W. BUEL, J. E. WILLOUGHBY, S. S. ROBERTS, C. P. HOWARD, JAMES D. MORTIMER, CHARLES S. CHURCHILL, M. H. BRINKLEY, H. M. STONE, S. WHINERY, PHILIP W. HENRY, CHARLES HANSEL, AND D. W. LUM,

Mr. Lavis.

F. LAVIS, M. AM. SOC. C. E.—This report is entitled "Report of the Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property," etc., with the sub-title "Valuation for the Purpose of Rate-Making." The speaker agrees that it is an important contribution to the literature of valuation; he thinks it unfortunate, however, that, at least by inference, it fosters the belief that the principles formulated and proposed can or may be used in the valuation of railways for the purposes of rate-making.

The title and designation of the Committee, as well as the proposal for its appointment, leave no doubt that the valuation of the railways was uppermost in the minds of the Board of Direction when the Committee was appointed; it seems unfortunate, therefore, that only one railroad engineer was appointed on it.

In view of the nature of the report, the speaker is strongly of the opinion that it is unfortunate that the word railway or any reference to the railways or their rates was permitted to appear in connection with it. He suggests that either the question as affecting railways be entirely eliminated, and a clear statement made at the beginning of the report that such is the case, or that the Committee be increased by

* Continued from March, 1914, *Proceedings*.

Mr. Lavis.

the addition of three or more members of wide experience and training in railroad location, construction, maintenance, and operation. Such contribution as the speaker offers in the discussion which follows, is directed more particularly to pointing out what he considers to be unwarranted inferences in regard to the valuation of railways which might be drawn from the report.

It is noted that in the report the expressions "physical valuation of property" and "valuation of physical property" are used quite indiscriminately. One of the fundamentals of the establishment of principles is the definition of terms. It is suggested that the Committee establish the use of the expression "valuation of physical property" to mean the establishment of the value of the inventoried items, without consideration of the so-called intangible values; also, that in speaking of the determination of the value of the property as a whole, that is, as a going concern, the word "valuation" or "appraisal" be used alone, without the addition of the word "physical." As an instance of the confusion of terms, it may be noted that the Committee includes "the cost of development" in what it calls the "physical value." This cost, of course, is part of the value of the property, but is hardly of the same class as the value of the rails, ties, etc., which are physical. The statement is made that physical valuation "does not furnish a satisfactory basis for rate regulation", but that other things must be considered. What is meant, presumably, is that other things than the value of the physical property must be considered. Among these items are mentioned location, design, and efficiency of operation, but it is admitted that the formulation of principles whereby values of these items may be determined for the purpose of rate regulation is somewhat difficult. Mr. Gibson in his discussion* also advocates the inclusion of such intangible items as strategic location, efficiency, etc.

The speaker has pointed out, in his discussion of the paper† by W. J. Wilgus, M. Am. Soc. C. E., the fallacy of the supposition that rate regulation of any individual railroad could be based on the result of any valuation of any kind; and his point of view and its reasonableness have been specifically and in detail publicly confirmed since then by the Hon. Charles A. Prouty, of the Interstate Commerce Commission.‡ It is out of the question, of course, to assume that the efficiency of the management of, say, one of the four through lines between New York and Chicago could affect its rates, or that its physical characteristics, as shown by its profile, alignment, or length, could do so. These things are items affecting the values of the different lines, but not their values for purposes of rate-making, or even rate regulation.

* *Proceedings*, Am. Soc. C. E., for February, 1914.

† *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 283.

‡ An address before the U. S. Chamber of Commerce at Washington, D. C., February 11th, 1914, *Railway Age Gazette*, February 13th, 1914.

Mr. Lavis.

A most excellent exposition of the various factors governing the establishment of the rates on railroads has recently been contributed by Mr. G. C. Hand,* the details of which it is not necessary to repeat, suffice it to say that he shows clearly that railroad rates in the United States are based on such a variety of different factors, including competition of different lines between the same points, a limited maximum which can be charged to move certain business, the accessibility of markets, balance of traffic, etc., etc., that neither the value nor the cost of service, nor the value of the property involved, are more than one of several factors—and often subordinate ones—in the determination of the rates on any individual railroad.

The Committee has quite wisely taken the position that valuation—of railroads or other property, as a whole and as a going concern—may, and should, be governed by the purposes for which it is made, and realizing the vastness of the subject decided to limit the scope of its inquiry. The speaker ventures to suggest, however, that the subject might well have been, and still might be, narrowed down to the consideration of the question as affecting the determination of the values of the physical property of railroads, or that the railroads be left to their own resources in working out their own salvation.

It is perhaps pertinent to the discussion to point out that though the valuation of the physical property of the railroads is very largely an engineering work, the valuation of the whole property of our railroads can only be properly made by a combination of financial, legal, and operating experience, combined with engineering; and that any committee of this Society would do well to hesitate before formulating principles for the determination of values other than of the physical property.

The Committee has devoted 18 pages of its report to the subject of depreciation, and this has been followed by a further supplementary statement of 18 pages on the same subject, and certain tables have been presented in the addition to the report. Appreciation is disposed of in 2 pages, and its discussion is practically confined to the consideration of increase in land values. The speaker, in his discussion of Mr. Alvord's paper,† expressed the belief that the physical property of any of our first-class trunk-line railways is worth to-day as much as, if not more than, its cost of reproduction new. Mr. Wilgus has expressed a similar belief in his discussion of this report, and it is undoubtedly held by every railroad man of experience, yet we are asked to believe, not only that valuations showing the present fair value of our railroads as only 85% or 90% of the cost of reproduction new are correct and just, but that rates should be based on these values.

The speaker believes that depreciation must be deducted in order

* *Railway Age Gazette*, February 27th, 1914.

† *Proceedings*, Am. Soc. C. E., for January, 1914, p. 191.

Mr. Lavis.

to obtain the true value of the physical property, but he also urges a more careful consideration of appreciation, and allowance for omissions in the inventory, which he believes will show the final value of the physical property alone of an established and well-maintained railroad to be at least 100% of its cost of reproduction new.

As regards the railroads which are not efficiently maintained, a decrease of rates on account of decreased value of the property will not build them up.

This, however, is aside from the main contention of the Committee's report, which deals with the methods of determining an annual charge as a proper allowance for rate-making. So far as the railways are concerned, a much more correct expression would have been renewal charge, or allowance for renewals.

The very clear and illuminating statement* of Mr. Jared How, as to the contractual obligation of the railroads to keep their property at 100% efficiency, and the difference between the continuity of railway maintenance, as contrasted with the life of a pumping plant, for instance, is of much interest.

The determination of an annual charge for renewals on a railroad seems to the speaker to be taken care of quite satisfactorily by an annual charge of a certain percentage of the value of the property based on its estimated life, and there seems to be no use in introducing or attempting to introduce great refinements in the estimate of what this amount should be. The intricate calculation of sinking funds, compound interest, etc., together with an elaborate adjustment of the value to be allowed for the actual depreciation, the latter varying constantly with the assumed fair return and assumed life, does not seem applicable to railroads.

The property of a railroad must be considered as starting with a value of 100, reaching a certain normal state, and remaining constantly in that condition, being maintained there by yearly appropriations to cover maintenance and renewals. Theoretically, these appropriations would be nearly the same each year, but it is easily understood that they may well fluctuate slightly, and it is desirable that they should be able to do so.

There is really no question of compound interest, or sinking fund, or anything of the kind; there is a continuous yearly appropriation to keep the property up to standard efficiency.

The theory of the Committee, however, is based on property which starts at 100, decreases to zero, returns to 100, and so on, and where it is necessary to have set aside—no matter how the money may be kept or invested—a sum for this complete renewal or replacement. At first thought, it would seem as if this was true of any property, but in its application to a railroad, it seems to the speaker that this question of

* *Proceedings*, Am. Soc. C. E., for February, 1914.

depreciation is so mixed up with and related to maintenance that it can only be taken care of or included in and with maintenance expenses, or virtually as an operating cost, and this is where the railroad situation differs materially from that of other types of public utilities. For instance, the cost of renewal of rails and ties is closely correlated to and dependent on not only the quantity and kind of ballast in use, the quantity of track work performed, the climatic conditions, weather, etc., but also on the type and condition of the rolling stock and the amount of traffic. Mr. Lavis.

It may seem to be theoretically possible to take a structure like a large bridge, a great terminal, or similar large item, and calculate a sum to be set aside yearly to replace it, but really the very uncertainty of the length of their life makes this utterly impractical in application.

In a general way, it is known approximately what percentage of the total value of the physical property of railroads should be set aside yearly for maintenance and renewals, and, for all practical purposes, it seems to the speaker that this percentage, based on the experience of many years, is as near as we can come to fixing a fair value for this allowance.

If it is necessary to go into further detail, each item composing the railroad may be tabulated, its life approximated, a value fixed by deducting the scrap value from the cost new, and the yearly charge determined by dividing this value by the estimated life. The bases of these calculations, however, as will be readily seen, are so indefinite and subject so much to judgment and individual experience, that greater refinement than this seems useless, and, as in the case of railroads, this money is actually—no matter what the theoretical case may be—used up each year, it is no use to establish elaborate methods of providing for compound interest, etc.

The Committee has advanced the *reductio ad absurdum* argument, that certain methods of estimating this percentage would mean that the property owners would have, at the end of, say, 10 years, $250 worth of property for every $100 invested. As a practical proposition, however, there seems to be little danger of this, so far as the railroads are concerned.

There is little need to fear, as Mr. Bates* seems to, that fair and adequate regulation of the railroads by the Government will result in the spoliation of the widows and orphans. In spite of the general efficiency of the management of our railroads and the integrity of their officials as a whole, there are not lacking examples of some neglect by them of the interests of the large body of stockholders whose holdings are so small as to deny them effective representation. The speaker has had some experience with regulation in other countries, and he is in-

* *Proceedings*, Am. Soc. C. E., for February, 1914.

Mr. Lavis. clined to believe that the concentration of the regulation of the railways in one national body composed of men not less just and fair than the best in the country, will be a benefit rather than a misfortune, and in this he believes most of the railway officials agree. It is really a national misfortune, that adequate regulation by the National Government was not undertaken from the beginning.

The speaker believes that the valuation of the railroads which has been undertaken by the Government, if it be properly made—as with the co-operation which the railroads are giving, it undoubtedly will be—will constitute a long step forward in the acquisition of that definite, full, and accurate knowledge which is necessary for a clear understanding of the situation, which knowledge is not now possessed by any one, neither the Government, the general public, the stockholders, nor even many of the officials and directors of the railways themselves.

How this knowledge is to be applied to regulation is not clearly seen by any one just now, but the study and the knowledge obtained will undoubtedly help to a clearer view. It seems that it can only be applied to rate regulation in the most general way, and, therefore, as if the work of the Committee might well be directed to the determination of the principles governing the valuation of the physical property alone, this inventory and valuation to be made in such a way that it may be used as a basis for any of the purposes to which valuation may be applied.

Mr. Phillips. H. C. PHILLIPS, M. AM. SOC. C. E.—The speaker regards it as exceedingly unfortunate that the Special Committee assigned to prepare a report formulating the "principles and methods for the valuation of railroad property and other public utilities", after more than a year of silence, and with no inkling of the change of direction of its labors at the Annual Meeting of the Society on January 15th, 1913, should have so limited the subject as to bring into it conditions which, as far as railways are concerned, tend to weaken the whole discussion.

With regard to the report as applied to public utilities which by their nature are somewhat in the class of protected monopolies, or, at any rate, have a well-defined sphere of action, the speaker has no criticism to offer. However, the Committee on the title-page of its report indicates that its subject is "Valuation for the Purpose of Rate-Making", and, further, that railroad properties are included throughout its report. With the exception of trolley lines, rather free from competition and more or less local in their nature, the speaker, in a study of valuation subjects extending over the past two years, has been unable to find any place where valuation has been used in the determination of rates on railroad properties, and though it is entirely true that valuation has been held by the Courts to be the test as against confiscation by rates made on altogether different principles, the

rates of a railroad have been, and of necessity must be, based on many other factors, and valuation carries a very small and insignificant part in the determination of such rates. Mr. Phillips.

To members of the Society having had railroad experience, it is hardly necessary to point out that the factor of competition as between railroads, places, and commodities, and, to a lesser extent, the cost of performing the service, have been and will be the leading factors in the determination of railway rates, and the only point at which valuation becomes a live issue in connection therewith is to determine whether rates made as outlined, or on other principles, are or are not confiscatory, and the fact that in one of the leading rate cases of recent times, where valuation has had its day in Court, the conclusion was finally reached that one of the three roads under consideration would be justified by its valuation in charging higher rates than the other two, if it could obtain them, which, of course, as a practical matter, it cannot.

With this in mind, it seems as if the Society as a body would be exceedingly ill-advised to urge as the result of its deliberations a conclusion that railroad rates are or can be based on valuation, and the report, therefore, should be confined to public service properties (on consideration of which it is mainly based), which by their very nature are limited and protected in their field of activity, and no attempt should be made to cover rate-making for railroads which is based on far different considerations.

WILLIAM W. CREHORE,* M. AM. SOC. C. E.—Broadly speaking, the subject adopted by the Committee for its report, namely, Valuation for the Purpose of Rate-Making, the subjects of certain papers which have been presented to the Society recently, namely, The Appraisal of Public Service Properties, The Physical Valuation of Railroads, The Depreciation of Public Utility Properties, and similar topics, all involve the one important question: How shall a fair basis be determined for the rates to be charged by public utility corporations? Mr. Crehore.

The Real Question.—First, what is the true basis for reasonable rates, and, second, on that basis, what are reasonable rates? When these two questions have been answered satisfactorily, the object of the present discussion will have been attained. The different phases of this subject are introduced to lead by different routes to different conclusions, but these conclusions must furnish an answer of some kind to the question: What are reasonable rates?

The point has been raised in this discussion that a definition of the term "value" must be adopted before it can be used intelligently, that the Courts have defined it in various ways, and that many of those taking part in this discussion have defined it at variance with the Courts. The speaker strongly recommends that some standard

* Previous discussion by Mr. Crehore appeared in *Proceedings* for February, 1914, on p. 380.

Mr. Crehore.

definition be fixed for the term, "valuation", which will be the understood meaning of the term, applicable to all purposes for which a valuation is to be used. To this it will be objected that years of custom and Court decisions have established a precedent requiring property to be valued for taxation in a different way from that required for rate-making or for acquisition. So far as we are bound, by law and Court decisions, to follow certain courses of action, there can be no discussion as to our duty, but being thus bound should not prevent our careful consideration of the propriety of existing laws and customs, or an attempt to change such laws and customs whenever it can be shown that a change would be beneficial. To set aside this whole question with the statement that the conclusions of one's opponents do not conform with existing laws and customs is not argument. The expediency of asking for a change of prevailing law involves a discussion of the effects which would follow such a change, and it is certain that no change for the better will ever be adopted unless convincing arguments are brought forward to uphold its expected advantages, and necessarily such a discussion must precede the campaign of education required to bring about the change.

The Term "Physical Value".—To approach this question with an open mind it should not be taken for granted that a proper basis for rates need be valuation of any sort whatever. The real valuation may be found to be something which is not at all suitable for a rate basis. Entirely apart from the question of valuation, and after its determination, it should then be decided whether or not the true valuation is a proper basis for rates.

It seems to have been pretty well agreed by the majority in this discussion that the intrinsic or tangible value of any property is not its "Sales Value," nor its "Original-Cost-to-Date Value", nor its "Cost-to-Reproduce-New Value", but that it is its "Cost-to-Reproduce-Less-Depreciation Value". The term "intrinsic value" denotes the inherent value, the value residing in the property itself, the tangible value, as distinguished from extrinsic or intangible values, such as good will and other elements of value attaching to the property by virtue of its association with other property, or for some other reason, but not values inherent in the property itself. It will be noted in passing that, under this definition, depreciation could not logically be included in the intrinsic or tangible value of property.

The preceding general discussion has been characterized by much indefiniteness on the point of what constitutes the physical value. Some have attempted to make the term cover intangible values besides the intrinsic value, and others have restricted its use to the intrinsic value alone. Still others have included within its scope all the intrinsic value and a part only of the extrinsic values, expressly excluding certain intangible values. For the most part, it seems to be the general intent

Mr. Crehore.

to restrict the term "physical value" to the intrinsic or the actual tangible value of the property.

The sales value usually includes something for extrinsic or intangible values, and yet, depending on the prosperity of the business or the value of the property due to its association with or separation from other properties, the sales value may either exceed or fall short of the intrinsic value of the property. In the majority of cases, the selling value constitutes a contract agreement between the two parties interested, and their individual circumstances at the time of the sale will sway the price one way or the other in spite of any estimate that can be put on such property. The selling price, however, is influenced most of all by the earning capacity of the property; and, as has been pointed out several times, as we are seeking a basis for regulating the earning capacity, it would be reasoning around in a circle to offer to determine that basis by the very element we wish to make dependent on it.

The merchandise in every modern store is inventoried by the Cost-to-Reproduce-Less-Depreciation Method once a year or oftener, and yet no one would think of buying out a prosperous merchant simply by paying him for the physical value of the goods on his shelves. There must be a further payment for certain extrinsic values, including the good will of the business. The feature of good will and other extrinsic values, in the case of a highly prosperous monopoly, may constitute by far the largest asset, the intrinsic or physical value of its real property being immaterial by comparison. What is it, then, that gives any extrinsic or intangible value to property? It is the earning capacity tempered by the risk involved in its ownership. When a man buys stock, all he wants to know is how much income he can expect from it, and the reputation of the corporation. Satisfactory answers to these questions do not need to be supplemented by information as to the amount of capitalization, the value of the assets, etc., etc. The corporation may not have any assets in sight except the good will of the business, and yet the stock may be a first-class investment.

Physical or Intrinsic Value Inadequate as a Basis for Rates.—It is plain that the physical value, that is, the intrinsic value of property of all kinds, can be estimated with a fair degree of accuracy, but that the extrinsic or intangible value depends for its size directly on the earning capacity of the unified business taken as a whole. As we cannot seek a basis for regulating the earning capacity in something that is dependent on that earning capacity for its very existence, there is no part of the value available as a basis for rates except the bare physical or intrinsic value of the property. As already stated, it is not necessary that valuation of any sort be made the basis for rates, but it is apparent that if rates are based on the bare physical valuation of the property, without any allowance for return on certain intangible values, the return on the investment will not be adequate.

Mr. Crehore.

Many items of intangible value have cost the investor large sums of money. Articles of trade often have to be given away to introduce them to prospective customers. Advertising is very costly, and some business enterprises require two or three years of advertising before they can show a profit on their sales account. There is nothing to show for these and other large initial expenditures except intangible values, generally designated as the good will of the business. Yet, in some lines of business, the good will is the chief asset, because the actual amount of tangible property required to keep them going is so very small. The professional man with a large and lucrative practice would certainly not care to sell out for the value of his tools or other physical assets required to keep up his business.

A toll bridge company may find at some stage of its existence that the physical value of its bridge and other property less depreciation is $20 000, and yet may be able to show annual profits which, if capitalized at their present worth and treated as an annuity, would require a fund of $30 000 from which the equivalent of the present actual profits of the company could be withdrawn annually so that the fund would just be exhausted at the expiration of the life of the company's charter, the probable life of the bridge and the company's charter being coterminous. Such a fund would then be the proper measure of the total value of the property, including the intangible as well as the tangible.

Although the examples just cited may not be strictly applicable to the case of a public utility, it is well known that there are many hundreds of items which enter into the cost of launching any large enterprise, whether it be public or private, and some of these items never produce any beneficial effect on the business, while others more than make up for them and give it a very material intangible value, which is just as real and costly as though it were possible to see, feel, and estimate its items.

It is apparent that the earning capacity of any property is the vital point in the determination of its total value, both extrinsic and intrinsic; yet the intrinsic value only can be determined by the Cost-to-Reproduce-Less-Depreciation Method. As intangible values are indeterminate, except by means of the earning capacity, which is what we are seeking to fix, it therefore seems reasonable to conclude that a just and equitable value on which to base rates cannot be found. It must be assigned, or approximated, or guessed at. In truth, the problem of evaluating public utilities is the reverse of the ordinary problem met with in dealing with private corporations, and begins with a determination of the minimum return that can be offered to attract capital. A private corporation, on the other hand, is in business to make all the money it can for its stockholders, and is supposed to be regulated by the power of competition.

Mr. Crehore.

The Fair Allowance as a Basis for Rates in Excess of the Physical Value.—Mr. Grunsky, in his paper, "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates", said:

"Intangible values, of whatsoever nature, result from high earnings. In the case of public service corporations, they are arbitrarily created by agreeing to, and permitting, rates which produce a revenue in excess of the ordinary return on safe investments. They do not exist unless the rates are higher than those which would produce net earnings equalling an ordinary interest return on the properly invested capital."

An "ordinary interest return on the properly invested capital" is elsewhere spoken of by the same author as "the return on ordinary safe investments" like savings bank deposits or other investments of like character. Mr. Grunsky, in course of his able presentation of the subject, takes the ground that intangible values should be disregarded in making appraisals for rate-fixing purposes, but that the net earnings of a public service property should in some measure exceed the return from ordinary safe investments. They should, indeed. It is certain that capital could not be attracted at all to our public utilities unless there was a prospect of greater return than is offered by savings banks or Government bonds. As just stated, the public utility problem begins with a determination of the minimum return that can be offered to attract capital. In explanation of his position in this matter, Mr. Grunsky says:

"reference may again be had to the case of an owner of a public service property who invests only borrowed money. If he receives only such interest on the investment as he must pay to the bank, he will have rendered a service without compensation, except such as he may be allowed in salaries, under operating expenses. In such case, it would be a proper business arrangement to compensate him for the risk of loss which he assumes, and for his management, and to make this compensation in some measure proportional to the net earnings. If the owner in the cited case is a stock company, this compensation will be the only element giving value to the capital stock of the company".

As one method of fixing a basis for rates, when finally the physical or tangible value itself has been found, it will be possible to make rates on it so large that the return to the investor will include something for certain assumed intangible values, that is, the percentage of return may be made any desirable degree larger than the return on ordinary safe investments. Perhaps this is the method which would be adopted by those who contend that the physical valuation alone should be made the basis for rates. The trouble with this is that to allot a fixed percentage of the physical value as the return on the intangible values is to assume that these two values always bear the same ratio to each other, which is very far from true. Certain it is that, without some

Mr. Crehore.

allowance in the rates to remunerate intangible values, there would be little attraction for investors. The necessity for adding something to the purely physical valuation when used as a basis for rates is apparent; but, as to what that something should be, there has hitherto been no agreement. Although the different classes of public utilities would require different treatment in this regard, the speaker believes that some average basis could be worked out for each class by itself that would provide an adequate remuneration for those intangible values which originally caused the investors some material outlay.

The Investment as a Basis for Rate-Making.—One of the methods for fixing a basis for rates, seemingly overlooked in this discussion, is to determine the investment. This is not at all what is meant by the Original-Cost-to-Date Method of valuation. There is a clear distinction between the actual cost of all the property purchased by the corporation and the actual amount of cash or property contributed to its treasury by the investors. If the latter could be ascertained by any practical method of accounting, it would be the ideal basis for rates. There would be substantial justice by this method, for the application of it would work both ways. It would take care of the investors' rights, in the event of mismanagement or unwise expenditures of the corporation's funds, and it would prevent burdening the rate-payers with a load of fictitious capitalization. It would also return to the rate-payers the benefit to be derived from a reinvestment of any portion of the earnings and the unearned increment on land values, removing these valuable sources of appreciation from the investors and giving them to the community, where they rightfully belong.

Choice of Valuation by the Owner.—In view of the many unsatisfactory features surrounding and pertaining to all methods of valuation for rate-making hitherto considered, and in view of the enormous amount of labor and expense required to put any one of them into execution, the speaker again suggests for serious consideration the expediency of taking the owner's valuation of his own property and using that as a basis for rates. There should be an end to all juggling with the term "valuation". There should not be one kind of valuation for rate-making, another for acquisition, and another for taxation purposes. If the owner is made to look at the question from both sides, he is far and away the best expert as to the true value of his own property. The way to make him look at it from both sides is to require him to pay taxes on the same valuation that he is allowed as a basis for his income. Within certain limits, it should be the province of public authority to prevent grossly irregular and inappropriate valuations, but, in general, the owners of public utilities should be required to name their own valuation, with the understanding that it was to be used as a basis for rates as well as for taxation, or for acquisition, or for any other purpose.

Mr. Crehore.

Think of the problems it would eliminate. Who ever heard of a public utility paying taxes on a fictitious valuation of any sort if the opportunity had been given to swear them off? Would any public utility care to pay taxes continuously on the proportion of intangible values which it now claims should be rewarded in the rates? If valuations continued to increase, due to the capitalization of earnings, either past or future, at least the rate-payer would have the satisfaction of taking his share of the earnings on these increases through the tax budget; whereas, if utilities in general neglected or refused to declare these additions to their property for taxation, the rate-payers would stand exactly in the same position as if they owned these increases outright, and would enjoy a corresponding reduction in the rates on that account. In the last analysis, the public would remain in control, both of the tax budget and of the rate-making, so that any consensus of action, by the utilities overbalancing the situation either one way or the other, could be readily corrected at the proper time.

At least, while we are waiting the many years it will take to get a physical valuation of our public utilities, let us try the alternative of letting the owners set their own valuation, with the common understanding that it is to be used for all purposes where required.

There is another point to be considered: After the proposed stupendous task of valuation is finished and the returns are in, how long will it be before conditions will have changed so much as to require another similar valuation? General conditions will certainly call for a readjustment of rates periodically, and how can this be done intelligently on the basis of an out-of-date physical valuation? Is this task, which is already recognized as Herculean, going to be repeated as often as a readjustment of rates is required? Rather let us have the task divided up and discharged by the owners themselves who are intimately familiar with the conditions, and then it can be repeated as often as the convenience of the public and the interests of the utilities demand.

Frequent Rate Regulation Undesirable.—The magnitude of the interests involved renders it extremely undesirable that rates should be changed too frequently. To readjust them once in 5 years, immediately after the utilities had filed their valuations, would probably be often enough. It might be too often. It would be preferable to have the period between adjustments too short than too long, however, because, if not long enough, the opportunity may always be availed of to continue the same rates for another period. Reasonably frequent periods would give the utilities a better opportunity to readjust their valuations with regard to all the elements to be considered.

Excessive Bonding and Capitalization of Earnings.—Recently, the Interstate Commerce Commission called attention to the manipulation by the Chicago, Milwaukee and St. Paul Railroad Company of the accounts of the Puget Sound Railway Company, a subsidiary of the St.

Mr. Crehore.

Paul, saying that it was done for the purpose of misleading the public and creating a market for its new bonds. The Commission claimed that this was unnecessary, as the Puget Sound Company could show reasonable profit on its operations without any manipulation of the books, and was in fact on a sound basis, both financially and physically. The President of the Puget Sound Company forthwith explained to the public that the only manipulation of which the Company might possibly be accused was rendered necessary by an effort to obey the laws of the State of Washington, and, in so doing, the bookkeeping was forced to be a little out of compliance with the mandate of the Interstate Commerce Commission. A significant fact of the President's statement was that the Puget Sound Company's original capitalization had been $3 000 000, but when the construction of the Puget Sound Extension was nearly completed a mortgage for $200 000 000 was found to be necessary, and such a mortgage was thereupon issued. The excuse for the irregular bookkeeping previously mentioned was that, under the laws of the State of Washington, it was impossible to issue a mortgage for more than twice the par value of the capital stock of the Company, and, therefore, the capital stock had to be jumped suddenly from $3 000 000 to $100 000 000. Naturally, it would require an agile management to stretch out the hitherto reasonable and sufficient return on $3 000 000 so that it would look anything like adequate for a return on $100 000 000 in addition to the carrying charges and amortization of a $200 000 000 bond issue.

Now, the phase of this situation which challenges our attention is that any company or individual should have the hardihood to ask for a loan of $200 000 000 on property capitalized at only $3 000 000. The first reply to this is that the property was worth much more than the amount at which it was originally capitalized. Let us assume that it was. Let us assume that, by the reinvestment of earnings since the time of its organization, the property had attained an actual value of $100 000 000, the figure at which it was finally capitalized. Even then, the amount of the proposed mortgage was twice the value of the property, and its issue was specially sanctioned by a law of the State. Is there any private business, corporate or other, the managers of which would ask for and expect to get a loan amounting to twice the amount of the security offered as collateral? Rather is it more reasonable to expect that even the best terms obtainable on a mortgage of this kind would be one-half or 60% of the value of the property, instead of twice its value. Yet there are those who would have us believe that a public utility is on no different footing from that of any private corporation.

It seems that the financial managers of public utilities always rely confidently on a steadily increasing valuation of their property through the reinvestment of earnings. They assume that out of future earn-

Mr. Crehore.

ings they will always be able, not only to cover the current depreciation, but also to carry and amortize bond issues far in excess of the present value of the property, and pay a profit besides. In other words, they use bond issues instead of subscriptions to the capital stock, because in so doing they are getting capital free of charge from the public, and whatever profit they can make over and above the interest and sinking-fund payment on the bonds is so much clear gain without the expenditure of a penny to obtain it. Generally, in years gone by, the steady increase of earnings justified this tendency to rely on the future; but in recent years the rate-payer has interposed his veto against supplying capital as well as income. When the appraiser comes along to ascertain the physical value of such property and finds large accessions to it due to the investment of the proceeds of bond issues, the question naturally arises: Should the valuation of this property be credited to the corporation and be made the basis of rates charged to the public in addition to the carrying charges and amortization of the bond issues? The plain statement of the question indicates the injustice of the process, and yet this was, until very recently, and is even now, when not prohibited by law, one of the ordinary methods of financing a railroad.

The reinvestment of earnings over and over again for many years and the discounting of future earnings by bond issues have increased the value of railroad properties at the expense of the rate-payers all over the country far beyond the stockholder's actual investment, and often beyond the capitalization. The discussion of rate allowances must take into consideration the fact that an enormous percentage of the values now found to exist in public utility properties was contributed by the public in the form of excessive rates, and, instead of using this part of the valuation as a basis for increased rates, it should in justice be used as a basis for the reduction of present rates, so that the actual investors in the property would be adequately remunerated, whether they are the rate-payers or the subscribers to the capital stock.

There are those who say, in reference to this matter: "Oh, let bygones be bygones, but let us legislate for the future so that the public may not be forced to contribute capital as well as income to the owners of our public utilities". In urging this view of the matter, it is argued that the present stockholders would be the actual sufferers, as they have paid the current prices for their holdings, and the current prices were based on the earning power of the properties averaged over a period of years. It is this fact that has halted the Interstate Commerce Commission in its treatment of the question of capitalization of earnings, and it is this phase of the matter which perplexes all who have given attention to an analysis of this subject. To base rates on the present valuation of these properties would be a fair solution of the problem for the present security holders, but would be penalizing the

Mr. Crehore.

rate-payers by compelling them to contribute income to the security holders for that portion of the value of these properties for which the rate-payers themselves furnished the capital. For years the reinvestment of earnings, that is, of capital supplied by the rate-payers, has provided our public utilities with an argument for increasing the rates, whereas, on the other hand, it should be an equally potent argument for reducing the rates, if the public was honestly given the benefit of its investment.

The public's plaint, however, does not end here. It has been shown that often and often bond issues by public utilities have been refunded and carried indefinitely long after the property originally provided by their proceeds is worn out or has become obsolete. No effort has been made to retire these loans with the extinction of the property representing them, but they are refunded again and again, and are claiming their share of the earnings of the corporation for something which has long ceased to exist. If the depreciated or obsolete property has been replaced out of the earnings without an accompanying retirement of the bonds, is it not plain that the property and the bonds cannot both claim their share of the earnings without putting a double load on the rate-payer? Is it not just as clear, also, that the process of rolling up the value of the property year after year, like a big snow-ball, out of the earnings of the corporation, calls for continually increasing rates to provide additional income for the security holder derived from the rate-payer's own investment? Is it not evident that the more the rate-payer helps the corporation along on its capital account, so much the more is he penalized by having to pay rates which will cover an adequate income on the ever-increasing valuation? After some years of this cumulative process, the public is now paying rates which are enormously in excess of a reasonable return on the capitalist's original investment; yet the property value is there, and would appear by whatever means the valuation was undertaken. Furthermore, if this process continues in the future, there is no end to the advancement of rates; the more they advance the more they will have to advance to cover the income on their own advancement. It is automatic.

If the rate-payers are also the owners, then the capitalization of earnings is a perfectly proper procedure, and has the effect of automatically reducing the rates any way; but, if the rate-payers are not the owners, it certainly will not be claimed by any one that they should be called on to furnish all the capital used in the business. Then just how much of this capital is it proper and right that the rate-payers should supply, and how much should be furnished by the stockholders? The answer to this question will be one element of the basis for fixing the rates.

Mr. Crehore.

Water.—So far as the rate-payer is concerned, however, this load of furnishing the capital for public utilities is negligible in comparison with the one he is carrying as a result of fictitious valuation. This feature is one that the present campaign of rate-fixing is designed largely to correct, and the present holder of the securities will have to stand the "squeeze." There is no help for him in this regard, nor should there be. He may have been innocently drawn into the investment without a proper investigation, or he may have relied on the movement of stock quotations in forming his judgment of the value of his intended investment, but in any case he has lost by investing in something of which the value was fictitious, and there is no more reason for protecting him in this matter than for protecting the investor in a private banking business who found that foreclosure on certain loans hitherto believed to be impregnable had developed a large shrinkage. To attempt to save the present stockholder from loss in these cases would be saddling forever on the public an almost intolerable burden of fictitious values.

Considering this question broadly, however, such cases of overvaluation as have resulted from the rascality or deliberate manipulation with intent to deceive on the part of one man or a small coterie of men, might receive special treatment in order that the security holders in these enterprises may not be entirely robbed. It might be found feasible in some of these cases to divert some of the surplus earnings now being reinvested as capital and apply them to a gradual reduction of the holdings of innocent stockholders who were the victims of the rascality of the managers. This, however, comes more properly under the head of financial management, and is outside the topic now under discussion.

Land Values as Excess Earnings.—Even if the percentage of excess earnings taken from the public to be used as capital by the public utilities is small, it makes a large difference to the capitalist in the amount of his actual investment. Constantly adding to his holdings from the capitalization of earnings, the original investor finds his income increasing in times of general prosperity with the acceleration of a compound interest account, without effort or expenditure of his own. References have been made by several of those participating in this discussion to the treatment of land values in connection with public utilities, and Mr. Sparrow has handled this phase of the subject ably and clearly. Why should not the appreciation of land values be treated like values resulting from a capitalization of earnings? The unearned increment in the value of land is no more and no less a gift from the community than is the increase of capital from excess earnings. The added value of public utility property due to reinvestment of a part of the earnings each year has precisely the same effect as the appreciation of its land values, adding to the assets of the investor without

Mr. Crehore.

any expenditure or effort on his part. The only distinction that can be made between the two is that the unearned increment of the land costs the community nothing, whereas all additions to the capital account out of the earnings come directly from the community in the form of high rates. The speaker fails to see any reason why both these questions should not be accorded the same treatment.

It is just as true of any private corporation as it is of a public utility that the reinvestment of a part of the earnings as capital is a free gift from the community, but a private corporation maintains its rates (or is supposed to maintain them), in open competition with all others in the business, whereas a public utility is under contract with the State to perform certain functions in return for which it is accorded a practical monopoly in the district which it serves.

Is the Capitalization of Earnings Confiscation?—Opponents of the proposition to deduct the accrued depreciation from the value of public utility property in establishing the rate-fixing value are very sure that to exclude this depreciation from the rate basis would result in a form of confiscation of the owner's property. This has been loudly proclaimed, and argued with some force. Do those who take this position also find any evidence of confiscation of the rate-payer's property in the capitalization of earnings? If it is taking property from the corporation without due process of law, to exclude from participation in the earnings such capital as has been used up or has become obsolete, or such portions of existing capital as have been allowed to deteriorate and have not been kept up to their full valuation or are without the means to supply this lack, then it is no less confiscation to take from the rate-payer funds to be used as fresh capital on which no part of the return is shared with the rate-payer. The speaker does not think the term "confiscation" applicable to either of these processes, but believes that they are on the same footing with respect to the import of that term.

Efficiency Its Own Reward.—As intimated by the Committee, one of the most important of the intangible values, and one having an amount totally disproportionate to the physical value, even among utilities of the same class, is the item of efficiency. Of two public utilities having practically the same physical valuation, one may be far more efficient that the other in handling its business. A uniform percentage based on the physical value in each case would remunerate each of them alike, taking no account of the superiority of one over the other. It appears to some that such treatment would penalize the more efficient company and put a premium on inefficiency; but, would not the more efficient company find its reward in the resulting lower cost of operation, and would it not, even at the same rate of remuneration as its less efficient rival, by reason of its very efficiency, have a greater margin of profit left for its owners?

Mr. Crehore.

A uniform percentage on the total physical valuation, as the basis for uniform rates, would include an allowance for operating and administrative cost, so that the uniform rates would mean greater profits to the company having the lower cost. Of two utilities covering practically the same territory and serving populations of equivalent size, one might have its capital invested in thoroughly modern equipment of higher value and greater efficiency than that of the other. Appraisals of the two would show for one a larger physical valuation than for the other, and, consequently, the total general valuation for establishing the rates would be higher the more of these modern plants there were. If, as before, the allowance for rates was a fixed percentage which covered the total cost of operating as well as the reward to capital, then the more modern plant, with an equipment having admittedly a higher efficiency than that of the older plant, will reap a further reward for its investors by the lower cost of its operation. In the same way that all other lines of business are compelled by competition at certain times of their existence to discard old and worn out or half worn apparatus for new and modern appliances, just so a public utility finds its own reward in making the change.

It has been suggested in this discussion that if rates are adjusted for the highly efficient competitors in the same territory, the poorer of these will lose until they meet the competition. It is understood, of course, that rates will be based on an average of conditions and valuations representing all utilities in the same territory. On such an assumption the writer agrees with Mr. James that the stronger and richer competitors might be required to pay the State, in the form of taxes, all the excess over the earnings of their weaker rivals, such rebate to the State being arranged on some sliding basis that would preserve the required incentive to efficiency intact; and it would be well to go farther, and limit the time within which the poorer and weaker would be required to put their equipment on a modern efficiency basis or else have the protection thus afforded withdrawn. Rates must be made uniform, whatever system is adopted, and cannot be based on conditions which would suit a single utility or group of utilities in any one class.

Other Problems Concerning Rates.—There are many other problems more important in their results to the public than the problem of finding a rate basis. After the basis is found, rates must be adjusted to it; but, in the process of adjusting them, there are thousands of classifications of which to take account. In the case of railroads, the most complex problem of the whole is that of making the various classifications. These classifications now furnish the basis of nearly all the discrimination prevalent throughout the United States, and it is these classifications and other discriminations, rather than the economic law of supply and demand, that determine in a large number of

Mr. Crehore. instances the movement of traffic throughout the country. It is plain that freight rates cannot be made altogether proportionate to weight or bulk. Under such a uniform rule, many very cheap products could not be shipped at all, because it would cost more to transport them than they are worth. Even now, where such shipments take place, and the railroad company does not collect in advance, it may never get its money at all, because, on refusal of the consignee to accept the goods, the railroad would have only the value of the shipment to reimburse it. There must, therefore, be enough more profit in handling the better and higher class of goods to make up for the lack of profit in handling the cheaper goods.

This classification problem is a very complicated one, and this fact has been taken advantage of by the railroads very extensively to assess the public for all the traffic would bear, regardless of uniformity. The Interstate Commerce Commission has done a large amount of work in the past in adjusting these classifications, but still more remains to be done, and there always will be more to do. New questions are continually arising which cannot be foreseen, and, with the railroad companies presenting only one side of the case, it is the duty of the public to present its own side as clearly as possible for the benefit of those in authority who have the final adjudication of these matters.

Mr. Maltbie. M. R. MALTBIE, ESQ.*—There is one thing in the report which has not been mentioned but which seems to be of special value. The Committee has pointed out that the question of the amount upon which a company is entitled to a fair return, whether cost-to-reproduce-new or depreciated value, is inseparably connected with the method of computing the allowance for annual depreciation. Many writers have failed to appreciate the relationship between these two, and have used one method for computing accrued depreciation and another for computing the annual depreciation. The additional discussion by Mr. Stearns has emphasized the point made in the original report, and demonstrates conclusively that one cannot fairly adopt one method for determining accrued depreciation and another for determining annual depreciation. It would be grossly unfair, as shown by Mr. Stearns, to adopt cost-to-reproduce-new as a basis for reaching fair value, and the straight-line method of depreciation in computing the annual allowance.

There are many other factors which the Committee has similarly treated, and indeed, it is probably doubtful whether there are many factors (perhaps there may be a few) where it is possible to settle one question or determine one factor without reference to the determination of others. If the Committee had emphasized and reiterated no other principle, it would deserve our thanks and commendation, for writers and experts have been prone to slip from one thing to another without appreciating the interdependence of the different factors.

* Commissioner, Public Service Commission, First District, State of New York.

Mr. Maltbie.

The fundamental question in rate cases is the rate, and the determination of a fair and reasonable amount collected from the consumers or those using the utility. In order to arrive at this, it has been customary to determine the fair value of the property and the rate of return; but, after all, there is no one yardstick which will apply to all cases, and it is only by threshing out the various questions, by clearing the atmosphere, which is often befogged, that it is possible to determine the final outcome; and two plans may bring the same result, but one may differ from the other in practically every point. The report of the Committee indicates that this idea was fully appreciated, and it has attempted with great care and forethought to elaborate a statement of principles which will do justice to the public and to the company.

Mr. Floy.

HENRY FLOY, M. AM. SOC. C. E.—Before taking up the discussion of the Committee's report, it might be well to call attention to the impracticability of the method of valuing public utility property proposed by Mr. Crehore. This is to let the owner place a value on his property, with the understanding that the rate of return allowed and the taxes to be paid thereon shall each be figured at the same percentage of the value of the property. Although not having any investments in public utility properties, the speaker thinks that all the utilities would be glad to accept any such basis of valuation and pay taxes to the extent of 10, 20, or even a higher percentage thereon. A little reflection will show that, as taxes are paid by the public—the utility merely acting as a collector—the corporations would be perfectly satisfied to pay any amount in taxes, provided the same amount was allowed them for dividends. It will be seen, therefore, that such a method of valuation would be not only impracticable but manifestly unfair to the consumer.

With regard to the suggestion of Mr. Lavis that the membership of the Committee be increased by the addition of three railroad men, the speaker would heartily endorse such procedure, stipulating, however, that the new members be specialists in the matter of appraisals and rate-making—not merely construction or operating engineers. A further suggestion would be that the Committee have added to its membership at least one capable attorney who has made a special study of the decisions of Courts and commissions in relation to the matters covered by the report of the Committee.

An examination of the Committee's report shows the painstaking effort and high character of the work of its members. Credit therefor, and the thanks of the Society, are due the Committee, even though we may not agree with its conclusions.

The title of this report would lead one to expect that its recommendations could be followed in appraising existing utility properties. As a matter of fact, the report deals largely with methods proposed to

Mr. Floy.

be applied to corporations which have been very recently created or which may be established in the future.

The serious question before engineers at present, is, not what possible theories and methods may be developed for ascertaining the value and determining the depreciation of utilities yet to be created, but rather what methods of valuation shall be followed in appraising the many existing and long-established utilities.

Probably many engineers—and certainly the speaker—would not differ with most of the Committee's report and recommendations, provided such recommendations are applied only to newly created corporations in which investors have placed their money after due notice as to the methods which would be applied and the returns which would be securable therefrom. Few will find fault if a commission, following the Committee's recommendations as to the "tango" treatment of return—a dip at each successive step—can induce capital to invest under such proposed rulings, but it is absolutely unfair and illegal to attempt to saddle untried, theoretical methods on innocent owners, who have invested their money under conditions and upon assumptions entirely different from those now proposed by the Committee.

On this account, much of the report will be of but little help to the Profession in determining proper methods of valuing long-established, existing utilities. To be sure, the report recognizes the necessity of using the so-called "reproduction-cost-new" method of getting at the value of long-existing utilities, but the practical application of such method is only generally indicated.

Passing over the many excellent points in the report that relate to making up an inventory, preliminary, engineering, and development expenses, etc., it would seem as if the Committee was attempting, without sufficient reason, to sweep away many of the fundamentals that have been generally recognized and are now accepted.

The Committee seems to assume that interpretation of the decision of the Supreme Court in the Knoxville Water Company case is the only true gospel. The Committee then proceeds to argue that other leading decisions (more numerous, and as to which the interpretation is less debatable) of the same Court are in error and must be corrected to conform with the Committee's views as to the proper method of making valuations.

As is quite generally known, the Knoxville Water Company case was not adequately prepared, or well presented, in comparison with present-day knowledge of these matters, consequently, the resulting decision and many of its dicta have been erroneously accepted, both from misapprehension of the facts, and misinterpretation of the Court's meaning. If the Committee hopes to attempt the reversal of any Supreme Court decisions, it should attack some of the principles

claimed in the Knoxville decision, rather than those others, which relate to cases that were more adequately prepared, better presented, and more recently decided. Mr. Floy.

In considering any decision of the Supreme Court, it must be borne in mind that the Court is passing on the particular case in question, and any conclusions reached are based on the peculiar circumstances surrounding that particular case. Consequently, too much importance should not be attached to the decision of the Supreme Court in some particular case when attempting to arrive at fundamental principles, which may be applied generally. Although it is true that the last word in any particular instance rests with the Supreme Court, and that such Court is given to following precedent, nevertheless, it cannot be presumed that the Court will seek to perpetuate what may be demonstrated to be a wrong, merely to avoid reversing itself.

No question can be regarded as finally settled, until settled equitably. The reference by Mr. Humphreys to the decision of the Supreme Court, in the Consolidated Gas case, that to maintain a pressure of 2½ in. of water in the gas pipes in a distributing system, "the mains and other pipes would have to be strengthened", is so contrary to fact that eventually the Supreme Court must reverse itself in this matter. In the same way, the statement of Judge Hughes, in the Minnesota rate cases, to the effect that "We also think it was an error to add to the amount taken, as the present value of the lands, the further sums calculated on that value, which are embraced in the items of 'engineering, superintendence, legal expenses', 'contingencies' and 'interest during construction'"; or again, the statement in the same decision, "It is impossible to assume, in making a judicial finding of what it would cost to acquire the property, that the Company would be compelled to pay more than its fair market value. It is equipped with the governmental power of eminent domain", is so contrary to common knowledge and experience in railway construction that the establishment of such principles cannot be accepted, even when attempted by the Supreme Court.

The Committee seems to require some legal support for making deductions from reproduction-cost-new, and, therefore, ties to the Knoxville case, and has developed a unique theory of estimating and providing for depreciation, the allowance therefor being stated to be "in effect, a payment from the rate-payer to the corporation of a part of its investment" (page 32). This is certainly a novel definition, and one that is contrary to accepted practice. The Committee, without apparent warrant, remarks (page 72), with reference to its proposed "Equal-Annual-Payment Method of Determining Depreciation Allowances", that "this method conforms to the decisions of the highest Courts". No references are given as to what Court decisions are

Mr. Floy. considered by the Committee, to justify their proposed method of annually increasing payments to be made by the rate-payer on account of depreciation and decreasing his payments for fair return. The Supreme Court certainly disapproves any such method as that proposed by the Committee, and the speaker suggests that the Committee produce the opinion of a competent attorney to the effect that any Court decision rendered to date is based on any such theory of ascertaining present value as proposed by the Committee's "Equal-Annual-Payment Method".

It is conceded that the decisions of some Courts hold, that, in determining the value of property on which to fix rates of return, deduction from cost of reproduction new, on the basis of a more or less theoretical computation, should be taken into account, but this is not the ruling of the United States Supreme Court. This particular question, with reference to whether the amount of depreciation of physical property was to be determined from actual inspection or from calculations based on life tables, was squarely involved in the Consolidated Gas case and definitely passed on by the Master appointed to take the testimony in that celebrated case. The total valuation of that property was some $56 000 000. It was shown that an expenditure of $604 988 for "repairs" (less than 1%), would make the plant as good as new, and this is the only sum that was deducted from the reproduction cost new, notwithstanding it was most vigorously contended by the plaintiff in that case that a further deduction of millions of dollars should be made for theoretical or accruing depreciation. The Master, in answer to this contention, says:*

"For the purpose of determining present value, however, particularly on the basis of cost of reproduction, the method followed by Mr. Marks [witness for the plaintiff who used theoretical depreciation based on life tables, similar to those proposed by the Committee] does not commend itself. It appears from the record, without substantial dispute, that while certain of the plants and apparatus may not be in perfect repair, they are, as a whole, in efficient operating condition, and that a large proportion of their capacity is represented by the latest pattern of water gas apparatus installed within the last few years."

The Master, in this case, in dealing with the alleged necessity for a reserve fund to provide for "final renewals" when the life of the apparatus should expire, says:

"Of course, the requirement of such 'final renewal' provision affects in no way the present value or efficiency of the plants of the company as operating concerns, except to the extent of the repairs [$604 988 above mentioned], which would be required to make the operating plant as good as new."

* Master's report, p. 110.

Mr. Floy.

The Circuit Court and the Supreme Court sustained in all respects the valuation fixed by the Master in this case, except on the question of franchises.

It is thus seen from the foregoing decision that property which is in good order and operating efficiently, although not new, need not necessarily be depreciated, at least in rate cases.

It is sometimes contended that the decision in Knoxville *v.* Knoxville Water Co., 212 U. S., 1, decided the same day as the Consolidated Gas case, holds a different doctrine, but a careful reading of that case, in connection with the Master's decision, shows otherwise.

Depreciation which can be determined by "a detailed examination of the property as it stands to-day,"* covers that deterioration due to inadequacy, obsolescence, deferred maintenance, or property not actually used in the service being rendered. It is these various classes of depreciation just specified, and not theoretical calculations based on office records as to date of installation, that are referred to by the Supreme Court in the Knoxville and other cases where the specific statement has been made to the effect that depreciation must be deducted in determining the values of property to be used in fixing rates. In the Knoxville case, the Master stated that he had added "complete and incomplete depreciation" to the present value of the surviving parts, in order to obtain the total value used as his basis for fixing rates. Consequently, the Supreme Court very properly criticized such procedure. It was equivalent to taking the depreciated value of the existing property and adding thereto the cost of all property which has been used in the past and which no longer existed, the value of which under adequate rates, should have been repaid to the investors out of revenue as a part of operating expenses, during the life of the now superseded property.

The Supreme Court says that the Master erred in adding the sum of "complete" and "incomplete" depreciation to the depreciated present value; it does not state that he would have erred in adding only "incomplete" depreciation to the depreciated value. The Court could not have considered that adding the amount of "incomplete" depreciation to the present depreciated value would have been error, otherwise it could not logically have stated that renewals must be paid for out of revenue as part of operating expense, for,

"if a different course were pursued the only method of providing for the replacement of property which has ceased to be useful would be the investment of new capital and the issue of new bonds or stock. This course would lead to a constantly increasing variancy between present value and bond and stock capitalization, a tendency which would inevitably lead to disaster to the stockholder or to the public, or both."

* Master's report, Knoxville case.

Mr. Floy.

It is evidently the thought of the Supreme Court that present value and the amount of capitalization, as represented by stocks and bonds—that is, the investment value—should correspond, or tend to equal one another, which would not and could not be the case if "present value" were taken to mean present theoretical depreciated value. This view of the Supreme Court is in harmony with its decision in the celebrated Consolidated Gas case, where only observed, actual, evidenced depreciation, obsolescence, or deferred maintenance was deducted.

Nor does the decision of the Supreme Court in the Minnesota rate cases decide that theoretical depreciation should be deducted from reproduction new to arrive at present value as a basis for rates. This decision, so far as it dealt with the questions of valuation, has been quite generally criticized by men best equipped to form an intelligent judgment on such matters. There are a number of propositions in this part of the decision that certainly will not stand.

At page 457 the Court says:

"It is also to be noted that the depreciation in question is not that which has been overcome by repairs and replacements, but is the actual existing depreciation in the plant as compared with the new one. It would seem to be inevitable that in many parts of the plant there should be such depreciation, as, for example, in old structures and equipment remaining on hand. And, when an estimate of value is made on the basis of reproduction new, the extent of existing depreciation should be shown and deducted. * * * And when particular physical items are estimated as worth so much new, if in fact they be depreciated, this amount should be found and allowed for."

If this quotation means anything, it would indicate that the depreciation of the theoretical, estimated kind, which is normally "overcome by repairs and replacements" is not the kind of depreciation being considered by the Court, but only "actual existing depreciation." This is shown, for example, by the deduction for value of "old structures and equipment remaining on hand," after having served their useful life, and held, perhaps, for re-sale as scrap, or retained at full value in its books, by the corporation hoping to be allowed thus to increase artificially the "fair value" of its property on which the rate of return is to be allowed. In the use of reproduction new, "the extent of existing depreciation should be shown and deducted." This repeated use of "existing depreciation," and the word "actual" certainly indicates that class of depreciation which is in evidence, apparent to the inspector, and capable of ascertainment by examination to prove that it is "actually existing." The Court, further, expressly states that when "physical items are estimated as worth so much new," depreciation is to be deducted, "if in fact they be depreciated," and presumably not otherwise. In the very nature of physical property, it is impossible after it has once been installed that full 100% can be represented by all the parts, except for the service intended.

Mr. Floy.

In the foregoing quotation from the Supreme Court's decision, the statement is made that depreciation must be deducted on the particular physical items being considered "if in fact they be depreciated." It will be noted that the Court expressly raises the question as to whether or not there has been depreciation, by the statement "if in fact they be depreciated." Absolutely, in every case, if market value —regardless of value for service purposes—were considered, depreciation of physical property would commence the instant it was installed, and there could be no "if" in the case. The use of "if" by the Supreme Court clearly indicates that depreciation should be deducted from reproduction new, only in case depreciation is obvious, or if the quality of service rendered has been impaired by use or by exposure.

If there is one thing that the decision of the Supreme Court in the Minnesota rate cases clearly establishes, it is that unwarranted assumptions, speculative bases, and hypothetical conclusions, will not be accepted as facts by this Court. This expression of opinion runs all the way through the decision, and clearly indicates that the determination of value by artificial rules, formulas, and speculation, instead of by examination of conditions, ascertainment of facts, and positive testimony thereon, will not have weight or carry conviction with the Court.

As the Supreme Court is unwilling to accept artificial rules, formulas, and speculation in determining value, as proposed by the Committee's Equal-Annual-Payment Method, and has repeatedly reaffirmed its decision that the present value of real estate is to be allowed, it will be seen that the recommendations of the Committee in these matters are inapplicable and misleading, and should not be endorsed by the Society.

The Committee apparently fails to appreciate the fact that the value of land is a capital account, not an operating credit or debit. If investors are to be allowed none of the chances for gain under advantageous circumstances, and must stand those losses accruing from disadvantageous conditions, the rate of return must be increased, but this is very difficult of accomplishment. If the investor were guaranteed, under all circumstances, a fair return, there might be some merit in the argument that he is not entitled to profits from the unearned increment, but such conditions do not now, and certainly will not, obtain in the United States in the near future; consequently, valuations proposed to be based on such premises are impracticable. If the utility investing in real estate is not to be allowed the unearned increment, the result will be ownership by individuals who will lease the required real estate to the utility at increasing rates, corresponding to the present value of the land, so that, in any case, the public will pay a fair return on the present value of the land.

The existing desiderata in utility valuation and accounting are directness and simplicity. Strict cost of reproduction applied to all

Mr. Floy. properties dispenses equal justice; has been approved by the highest Court; and is direct and fairly simple in its application when used by fair-minded engineers. It has come to be generally recognized as meaning the cost of reproducing new, a definite, existing, physical property on the basis of prices current at the time of estimate—and such estimate is made up to include everything that can be inventoried —regardless of original cost, age, service value, or present condition, as affected by depreciation. Reproduction new has not been accepted as meaning the estimate of cost at present-day prices, under conditions contrary to those existing at present and based on historic conditions. The Committee may consider that a combination of methods, namely, reproduction cost new and original investment combined, may be a fair method of getting at the existing fair value, but, for such method, the Committee should originate a new term and not attempt to legitimatize their innovation by adopting a generally accepted and widely understood phrase. If "cost of reproduction new," as defined by the Committee, is applied to long-established utilities, the resulting appraisal would not only be contrary to the decisions of the Courts, but would result in confiscation of private property.

When once determined, the cost of reproduction furnishes the basis for a uniform fair return to the investor, as well as the amount to be used in estimating the regular yearly allowance to be included in the rate charged for service to be paid by the consumer in order to protect the investment and maintain the service. The method of handling this latter payment to cover depreciation is a matter of detail, which can well be left to the public utility commissions, or other regulating bodies, but is not involved in the question of determining the present value of properties not heretofore under Commission rule.

It must be recognized that the investor in utilities has not put his money in to have it paid back in driblets, as proposed by the Equal-Annual-Payment plan of the Committee. The investor has placed his money with the expectation of a uniform return therefrom, on the part of the utility in which he has become interested; it is unfair and irrational to ask that he now receive back this investment in small, annual payments, which must be placed elsewhere, in order that the investor may receive the fair return on the amount which he considered his original investment in the utility. The gratuitous assumption of the Committee that, under its plan, the investment will be paid back yearly only in such amounts as may be required for additions to the property, is so highly theoretical, and contrary to what will be found practical, that such scheme cannot be seriously considered in the attempt to determine a generally acceptable basis of valuation and return between the utility and the public.

Mr. Whitten's book, which was of such great aid to the work of the Committee, is a masterful collection of Court and commission de-

Mr. Floy.

cisions. Mr. Whitten, however, like most writers, has been unable to avoid all errors, as, for example, his conclusions with regard to the Court decisions in the Cedar Rapids Gas Light Company case and the Des Moines Gas Company case. His personal views and opinions are sometimes "against the clear weight of authority," as stated in a recent brief of a well-known attorney. Because of the evident dependence placed by the Committee on Mr. Whitten's book, the following quotations from a review of that book by the Secretary of the Committee is of interest.*

"* * * The author is well qualified for the work undertaken by him, which has been done fairly and without apparent bias, though in his expressed personal opinions the author leans to the public rather than the corporate point of view in his constant tendency to revert to original cost rather than present value as the most important yard stick for valuation.

* * * * * * *

"With reference to the cost of reproduction the author concludes:

" 'Considered from all points of view the method of reproducing the existing plant under the actual physical and other conditions under which it was actually constructed seems fair to both parties. It is a rule that corresponds to the actual equities of the parties, while the other rule gives an unfair advantage, in some cases to the public and in other cases to the Company.'

"Here speaks the exponent of the public who seeks to enforce the doctrine of valuation by *original cost* rather than by the legal rule of *present value,* advocated by the corporation, and in force in all private and general business transactions. In the light of the past trend of court rulings, would not a fairer basis of determining reproduction cost involve the reproducing from the old original conditions of the plant in its present condition? The author's definition involves the reproducing of the work actually done by the company, not perhaps of the existing structure.

"The author's discussion of 'actual cost,' the possibility of its accurate determination, and its utility as a standard of valuation is certainly not justified by conditions in many of the older communities of the East.

* * * * * * *

"In the discussion of 'Pavement over Mains' crops up again the strong bias of the public-service commissions in favor of original cost, rather than present value, as a standard of valuation. If the reader will constantly ask himself the question, 'Is this original cost or present value?' in reading the author's own comments and quotations from no less an authority than Commissioner Maltbie of the New York Public Service Commission, in the discussion upon the paving question contained in paragraphs 168 and 169, he cannot fail to be struck by the inconsistency of the position taken. It is unfortunate, too, that the issue should be clouded by any reference to ownership of the pavement.

* * * * * * *

* Review by Leonard Metcalf, M. Am. Soc. C. E., "Valuation of Public Service Corporations," by Robert H. Whitten, *Engineering News*, September 12th, 1912.

Mr. Floy.

"In the discussion upon 'Going Concern as Created Income,' the same strictures apply. The author prefers the Development Cost method of determination—clearly a reversion to original cost rather than present value. The author could not have been guilty of such a statement upon the reproduction cost method of determining going concern value as that contained in § 586:

"'* * * A public water supply is a necessity. A light system is a necessity. They are utilities that cannot be permitted to stop. The consumer must use them or suffer irreparable injury. *It is fanciful to speak of a development period for the new plant under these conditions.* If the old plant were wiped out, the new plant would have the business at once if already constructed, and otherwise, as soon as completed and ready for operation,'

"had he studied the actual experience of New Orleans, which has recently built new works, taken over an old small local plant, and in spite of drastic legislation requiring the abandonment of cisterns, is, in fact, *not in fancy,* slowly developing going concern value at substantial cost. So, too, his dicta upon going concern value:

* * * * * * *

"While the critic has no brief for either method and recognizes the inherent difficulties of the problem, the reproduction method of determining going concern value is the outcome of an honest effort on the part of the engineer to meet the requirement of the courts that the true reproduction cost shall be determined, and with all its possible inaccuracies, it is the only method yet devised which in any sense approaches such a determination."

The Committee has referred to the speaker's book, "Valuation of Public Utility Properties", using a quotation therefrom, as showing "the fallacy of the views expressed by engineers of much experience in valuation, that rates based upon the depreciated value of a property are necessarily lower than those based upon its full value." (Page 47.) As additional quotations from other writers are also given by the Committee, but without mentioning such writers by name, the exceptional honor thrust upon the writer would seem to be a little invidious. However, the quotations are from writers of such standing that to be classed with them and the Supreme Court in the condemnations of the Committee, offers no serious cause for complaint. The illustrations used by the Committee may disclose a fallacy in the methods proposed in its report, but they do not disclose any fallacy with regard to the practical matter of what is actually being done to-day in the valuation of utility properties and the fixing of rates based on such valuations. There are too many instances, known to those conversant with the subject, to need any citation here, in order to prove that the present theoretically depreciated value, where used for the purpose of fixing rates, results in a much lower return to the investor than if the full investment or the reproduction value new of the property had been

used for such basis. Therefore, the speaker's illustration does not seem to disclose anything in the way of a practical fallacy. Mr. Floy.

The soundness of the speaker's views as to the use of present value of land, inclusion of pavements over mains, and definition of cost of reproduction new, seemed to meet the approval of the Secretary of the Committee, at least, within the past year and a half, as shown by the following:

"The work of the commissions in determining land values is discussed in detail, as is the much debated question of the inclusion in or exclusion from reproduction cost estimates of the cost of paving over trenches, laid by the city subsequent to the construction of the pipe system by the corporation. The author points out the illogical position taken in this matter by some of our courts and commissions, and while admitting that in certain cases reproduction cost may not be a proper criterion of value, he soundly holds that in making an estimate of reproduction cost, the actual conditions of reproduction must prevail and the cost of the paving work be included, therefore, although not originally incurred by the corporation, as 'there exists no judicial pronunciamento for taking a part of the estimated cost of reproduction and leaving out the other part.' "*

The report (page 32) states that it is necessary to "adopt some practicable and equitable method of determining depreciation allowances" to meet certain requirements, which are given by the Committee. These stipulated requirements can be met much more simply and satisfactorily than by the adoption of the Equal-Annual-Payment Method. There is nothing in the requirements given by the Committee, which would prevent their being met by the use of either the Straight-Line, or the Sinking-Fund Method; which of these methods is preferable, on account of other considerations, need not be here considered.

One definite purpose of the Committee is apparently to provide equal annual payments by the rate-payers, continuously; and yet, as shown by the table on page 34, these payments are not equal, unless the same rate of depreciation and return is used. In order to attain this feature, which, in the minds of the Committee, seems so desirable, one of its members in a recent paper† states:

"I should like to suggest that the interest be the same on capital and depreciation allowances and that profit or wage be computed on cost of operation."

In order to have the report of the Committee acceptable to utilities, any requirement, that the rate of depreciation and rate of return should be the same, must be waived, and, as the greater the difference

* Review by Leonard Metcalf, M. Am. Soc. C. E., "Valuation of Public Utility Properties," by Henry Floy, *Engineering News*, September 12th, 1912.

† "Suggestions for Public-Utility Rate Making," by W. G. Raymond, M. Am. Soc. C. E., *Engineering News*, March 5th, 1914.

Mr. Floy. between these rates, the greater the inequality between the early and later years, during which the rate-payer is making payments for the service rendered, the recommendations of the Committee with regard to the treatment of depreciation must fall of their own weight.

Without discussing minor inconsistencies and other details with which the speaker cannot agree, it would seem as if the Committee was attempting to determine only one basis of "cost," which it considers should be used as the "value" of a given property. The Supreme Court requires that several bases of cost should be considered, and, by an act of judgment, the fair value then determined. It is on this account that the Committee's recommendation, mixing original-cost and original-investment methods, with reproduction-cost-new methods bring about a result which does not conform with any one of the valuations recognized by the Supreme Court. Such confusion is the cause of the Committee's conclusions that unless expenditures (many of which are not now ascertainable) have actually been made in connection with original construction, allowances therefor should not be included in the present value (page 28).

The recommendation of the Committee (page 43), classifying depreciation of property having a life of less than 5 years, as maintenance, and that having a life of more than 5 years, as replacement, is not progressive or in accordance with the best practice. The practical difficulty of separating maintenance from renewal accounts is generally recognized, and some utilities, with the approval of public regulating bodies, are now setting aside annually a lump sum to cover maintenance and renewals. Against this gross sum, the current year's maintenance and renewal expenditures are first charged and the balance of the appropriation is carried forward as a depreciation fund, for future renewals, thus simplifying the accounting, avoiding controversies between the representatives of the utilities and those of the regulating bodies, and insuring that the public receives full credit for all payments on account of depreciation.

The Committee proposes to depend mainly on calculated theoretical methods in determining depreciation, which do not give due regard to the condition of maintenance and repair in which the property may actually be found—regardless of its age. The Committee argues that the utility is only entitled to such allowance or depreciation as may have actually been expended (page 42), apparently failing to distinguish that the rate allowed for depreciation is entirely independent and distinct from the state of depreciation in which a property may be found to exist. Maintenance expenditures may almost wholly, if not entirely, offset losses from deterioration. Depreciation is but the sum of maintenance and renewal, and sufficient may be spent for these accounts to equal the full amount of deterioration.

Mr. Hendricks.

V. K. HENDRICKS,* M. AM. SOC. C. E. (by letter).—It seems desirable that the Committee should discuss more fully in the report the treatment of the enhancement in land values. As the writer understands Paragraph 19, Appreciation, on page 73 of the report, the public service corporation is to repay to the rate-payer the amount of the enhancement in values of land. As brought out in previous discussions, all other owners of property enjoy the benefit of such enhancement without having to pay for it, and the writer does not see why public service utilities should not be treated in the same manner.

Even if it were proper that the corporation should pay for the enhancement in value of land, there seems to be no way by which this payment could be made to the rate-payer at the time of such enhancement. Changes in land values are erratic, and there is no uniform change on which it would be possible to base any reliable calculations. If the public were paid for this enhancement by direct donation to the State or Federal Government, the payment would not be made to the rate-payer, but would be made to the general public. Such an adjustment would necessarily have to be made periodically, after the enhancement is known, and would be in the nature of a construction charge (or credit, as the case may be) and not in the nature of a refund to the rate-payer, or reduction in the rate.

As the writer sees the matter, the public service corporation should be entitled to the full benefit of enhancement in land values, and, even if this view is wrong and the Committee's view is correct, it seems impracticable to treat such appreciation "in the same way that the depreciation of the perishable property is treated, but on the opposite side of the account."

Mr. Wilgus.

WILLIAM J. WILGUS,† M. AM. SOC. C. E. (by letter).—Since the preparation of the previous remarks by the writer, the Committee has issued a supplemental report, which is summarized in the following paragraphs:

"It has already been shown in the foregoing discussion that, in connection with the Replacement Method and the Sinking-Fund Method of providing for depreciation, value new must be used in order to do justice to the owner of the property, and, for the reasons given, it would obviously be confiscatory if the value in such cases were to be depreciated from year to year.

"In connection with the Straight-Line Method of providing for depreciation, it has been shown that equity requires that the depreciated value be used. When this method is used, the rates necessarily decrease from year to year, the amount of decrease being small in the case of short-lived property and large in the case of long-lived property, but this decrease does not represent injustice to the owner of the

* Previous discussion by Mr. Hendricks appeared in *Proceedings* for February, 1914, on p. 850.

† Previous discussion by Mr. Wilgus appeared in *Proceedings* for February, 1914, on p. 366.

Mr. Wilgus.

property, as he will receive rates which, taken as a whole, during the life of the property, will be equitable. By the use of this method, he would receive too high rates when the property is new and too low rates when it is old, with a correct average amount.

"The Equal-Annual-Payment Method has been devised to obviate this difficulty, and when it is used in connection with the depreciated value of the property, as it must be to produce equitable results, the rates will remain constant regardless of the age of the property or the extent to which it has depreciated."

On railroads, except in the case of equipment, the restoration of depreciation of each item of property as it goes out of use is charged to current expenses, or, in some instances, to profit and loss surplus which may be looked on as the equivalent of a sinking fund; and therefore the methods referred to in the first paragraph of the quotation would apply thereto. Equipment renewals in part are charged to reserves, for which no standard practice prevails, some roads adopting very low rates and others comparatively high ones, all depending on the character of maintenance and the viewpoint of each company.

Utter confusion would follow any attempt to use both of the first-mentioned methods, and the third is believed to be inapplicable to railroad practice. Hence, the first method, of which cost-of-reproduction-new is the basis, is believed by the writer to be the only practicable and logical one to adopt, ordinary current depreciation chargeable to expenses to be defrayed out of current earnings, and deferred depreciation likewise chargeable to expenses to be provided through an allowance in the rate that will fairly compensate the owner for his assumption of the liability of making good such depreciation, as the need arises, without swelling the capital on which the public is expected to yield a fair return.

It is to be hoped that the report of the Committee, in its final form, will bring out clearly and forcibly its later views, which recognize that confiscation would follow the deduction of depreciation from cost-of-reproduction-new where the rates, coupled with the accounting regulations of the Interstate Commerce Commission and other regulatory bodies, do not provide for a gradual restoration of capital to the owner.

Mr. Dana.

RICHARD T. DANA, M. AM. SOC. C. E. (by letter).— The great weight which this report will have in the development of valuation practice, and in legislation connected with it, makes it of importance to eliminate, as far as possible, contradictions in terms and ambiguous interpretations of the fundamental facts that must govern any theory of this subject. Valuation is the subject of the report, and there are at least several kinds of value, yet the Committee seems not to have considered it necessary to define the term, value, which it has used in several senses. Most laymen fail to appreciate the fact that confusion

Mr. Dana.

in the use or meaning of this word is far more likely to result in injustice, or inequity, to the owner of a public utility plant than to the public, as will appear in the following.

Just as it has always been standard practice among engineers "to give the contractor the benefit of the (reasonable) doubt", so should it be the duty of appraisers to see that the owners of property receive rates which shall afford them a reasonable return on their property, and as long as the community presumes to substitute its own authority for the law of supply and demand, where free competition is not possible, just so long should it lean, if any way, toward the owner, in the determination to guard him against loss of his property by inadvertence and "without due process of law". It may be objected that the rights of the public must be conserved, which is true; but it is a common-law principle, centuries old, that before depriving a man of his property or of his liberty, the burden of proof is always on the community or the plaintiff. In a criminal action the State must prove its case beyond a reasonable doubt, but in a civil suit the plaintiff need only prove it by the weight of evidence. In these matters of rate-making the same broad principle of common-law justice, which for hundreds of years has maintained the sanctity of individual rights in all community matters, must sooner or later crystallize the practice into the same general form. The burden of proof should be on the community in all matters that are open to serious doubt as between it and the individual or corporation. The trend of practice is now plainly in this direction, yet many errors have been committed through failure to observe this rule.

The universal method in valuations is by synthetic estimates, in as great detail as possible. Now, the great fault of this method—perhaps its only fault—is that the likelihood of omitting items which should be included is far greater—a hundred times greater—than the likelihood of putting in items which should not be included. Consequently, every appraisal, other things being equal, is more likely to be too low than too high. The inclusion of a considerable percentage for omissions and contingencies is an effort to compensate for this inequity. Consequently, in a standard appraisal it is reasonably certain that the net amount of the omissions, as reduced by the allowance for omissions and contingencies, will be in small proportion to the whole amount of the valuation; but because there is to-day great confusion as to the meaning of the term, value, an owner may be deprived of a very large part of his property without compensation. The Courts in general will allow a "fair return upon a fair value" (page 6),* and it has been held (page 20),* "that the value of the property is to be determined as of the time when the inquiry is made regarding the rates". The Committee in its report infers that this implies that present (as of the time of the appraisal), rather than original, unit prices, should

* Committee's Report.

Mr. Dana.

be used in determining the cost of reproduction. Does this necessarily follow? The whole matter hinges on the meaning of "fair value", and the writer purposes to show that, with a logical definition of this term, the Committee's inference is untenable. The value of a plant is its intrinsic worth to its owner. Measured in money, it is "that sum which he could exchange it for without intrinsic gain or loss". As ownership exists for the purpose of periodical return (interest or dividends), the theoretically perfect method of computing intrinsic worth would be by capitalizing net earnings, but this is impossible for rate-making purposes, involving reasoning in a circle, as has been often pointed out.

The application of the definition of value just given affords a convenient criterion for testing the method of computing unit prices. By way of illustration, assume a private water plant, 60 years old, with a large reservoir excavated originally in earth. The earthwork cost probably 40 cents per cu. yd. by hand methods (old rates of wages), but could be done to-day for 30 cents (steam shovel and present rates). If the owner should exchange this reservoir for money, on the basis of 30 cents per cu. yd. for the excavation, he must stand a loss of 10 cents per cu. yd. It cannot be objected that the cubic yard which originally cost 40 cents to remove has depreciated "functionally" or "naturally", unless another reservoir could be dug for less cost or for the same cost with greater usefulness. It cannot be objected that he lost the 10 cents per cu. yd. as soon as the steam shovel was developed, and that the community is not responsible for what he lost before the appraisal, because he has not lost it until he parts with it, as long as it is useful to him in his business. If 10 years or 2 years before the appraisal the reservoir became useless, then at that time, he made a loss of the full cost, perhaps. If it deteriorated functionally, then there was a partial loss by depreciation; but with such functional depreciation, which depends on capitalized net earnings of the depreciated plant in comparison with those of a standard plant, the steam shovel has nothing to do. The cubic yard which was taken out by hand 60 years ago is bringing him the same income as if it had been excavated with a steam shovel. As it could not have been excavated with a steam shovel in those days, its actual cost represents the fair equivalent of what the owner has invested in it. If he receives less than this for it in exchange, he stands a loss. If he receives more, he gets a profit. If the community allows him 30 cents for it, it compels him to lose 10 cents, and deprives him of his property without compensation. He might be willing to sell it for 30 cents and take a 10-cent loss in order to go into a more profitable business, but the community has no right to make him sell it and take such loss.

From another viewpoint, consider a telephone company which owns, among other things, 100 000 000 lb. of copper wire on poles, for which it paid a weighted average price of 15 cents. Its investment in the wire will then be $15 000 000. Now, suppose that at the time of ap-

praisal the price of copper wire was 29 cents. If allowed rates on the basis of 29 cents, the company would get a profit of $14 000 000 on that item. It cannot be argued that the company made the profit as soon as the market changed and the open market price rose to 29 cents, as it reaped no benefit from the market rise if it could not sell its wire, but kept on telephoning over it. A profit sans benefit is of infinitesimal value. The company would have made a profit if it had sold at 29 cents, but had it done this, it would not have had the wire over which to telephone. The community, in taking over this wire at any other price than that which was paid for it, must either compel the company to take a loss or allow it to make a profit, neither of which alternatives is consistent with a fair "value". There will be some copper wire in the warehouses, say, 10 000 000 lb., which is not in use, is not earning anything, cost 15 cents, and could be sold in the market for 27 cents net. It does not have to be kept on hand for emergency repairs, but is held pending some proposed new construction. It differs from the wire on the poles in that it is exchangeable for cash at 27 cents without interfering with the operation of the company as a going concern. Its owner can sell it the day before the appraisal and "take" a 12-cent profit. This he cannot do with the wires on poles. If the community allows the company 15 cents for the wire in storage, it will compel it to part with the profit which it earned by speculating in copper (which is what it did when it bought in advance of its wants), and, therefore, it would be causing the company a loss on the exchange, which is inconsistent with the definition of a fair value. To avoid intrinsic gain or loss, the community should allow original unit prices for items which are not marketable by the owner without going out of business; and market sale prices for such items of plant as can be disposed of without interfering with the business. A corollary to this rule necessarily must obtain when a loss has taken place or a profit has been earned on plant in service. Mr. Dana.

It is possible for the owner to suffer a loss or gain a profit on the plant without having a free market for it. Depreciation entails a loss to the owner, and when it is a function of the lapse of time (natural depreciation) to avoid this loss, it must be compensated for, either by a sinking fund, to increase *pari-passu* with the depreciation, or by an equivalent amount invested in some other manner, such as other plant (renewals), etc. On appraisal, the depreciated items always entail a loss which was incurred by the owner before the appraisal and with which the community has no concern, as such loss is not a result of the appraisal. If the owner has kept his investment intact by a depreciation fund or by purchasing other plant or investing in some other manner the equivalent of the depreciation sinking fund, then the value of the total assets remain as they were, but the part of the plant which has depreciated has already stood the owner a loss. The community must allow its depreciated value, in rate-making, else it would be

Mr. Dana.

standing part or all of the loss already incurred by the owner during the years of operation, which is against the hypothesis in the previously given definition of value. In relation to this matter, two points must be very carefully noted: First, that natural depreciation is a loss of value, proceeding gradually, which cannot be determined by market conditions, nor even by inspection of the plant, but must be calculated theoretically on certain assumptions of life, age, and interest rate; and second, that the capital may be preserved intact by a separate depreciation fund to be set aside (a very rare occurrence in practice), or by investing an equivalent amount in other plant or in some other asset, or again by a part of the potential increase of business caused by the money spent in development (or not paid in interest or dividends during the early years of the business) and which has been termed "development expense". Considered in this manner, there is no difficulty about constant rates and constant dividends, without impairment of capital and without departing from a consistent definition of value. If the owner has foolishly wasted money in accordance with bad practice, he is not entitled to have it covered by development expense, as it is not a proper expense of development.

There remains to consider functional depreciation. Consider a 30-year, single-cylinder, non-condensing, steam engine belted to a modern generator. Assume the engine to be in perfect condition and functioning as well as on the day on which it was first placed in service. It is transforming steam power into mechanical work at a certain rate and at a certain unit cost for that function. Nothing has been spent on it in that time except for care, housing, and ordinary repairs. It could not be sold except for scrap. No fund has been set aside with which to buy a new engine in its place. A modern engine of the same capacity can be bought, which will transform steam power into mechanical work at a unit cost which is to that for the old engine, say, as n is to m. These unit costs do not include interest, etc., on the prices of the engines. The new engine could be bought and erected for N dollars. The amount which represents the fair value of the old engine is that figure which will make the unit cost of transforming energy by the old engine the same as that of transforming energy by the new engine, if bought. Otherwise, if the new engine can transform at less unit cost, the owner could exchange and make a profit; but, on the other hand, if M be such a figure that the interest charges and operating expenses of the new engine would be greater than for the old, a compulsory exchange would result in a loss to the owner.

Let the cost of the new engine, connected. . . . . $= N$
" " value of the old " . . . . . $= M$
" " unit cost of transforming power by the new engine $= n$
" " " " " " " " " " old " $= m$
" " number of units of power transformed per year. . $= U$
" " interest rate on money. . . . . $= r$

Then the annual cost of operating the new engine would be $Nr + nU$..(1) Mr. Dana.

" " " " " " " old " " " $Mr + mU$..(2)

" " unit " " " " new " " " $\frac{Nr}{U} + n$...(3)

" " " " " " " old " " " $\frac{Mr}{U} + m$..(4)

By the conditions of the problem these must be equal, and, therefore,

$$\frac{Mr}{U} + m = \frac{Nr}{U} + n, \text{ whence, } M = N - U\frac{m-n}{r} \ldots\ldots (5)$$

It can be shown that this is the same value for M which would follow from equating the capitalized annual cost of operating the two engines.

The owner of a certain water plant thinks that it is worth more than $100 000 to him; the mayor of the city thinks that it is worth $50 000 to the city which wants it and has the right to acquire it on a valuation by disinterested experts. The city would scrap a large part of it and have an entirely different kind of works, and considers itself justified in allowing scrap value for all the parts of the plant that it would like to scrap, on the ground that the new plant would pay for itself in a few years out of increased net earnings. The city's adviser estimates that for a certain pump the value of M is actually negative. On this theory it would be consistent to allow the owner less than nothing for the "value" of his pump and of any other plant which, by this formula, will be less than nothing. The solution may be found by applying the criterion that "value is that sum which can be exchanged for the plant without intrinsic gain or loss to the owner". The pump is raising water which is being sold for more than the operating costs. The owner is receiving a return on the money which he has invested in the pump and the remainder of the plant, and he is now receiving some return on money spent in developing the business, by way of Development Expense. The pump in question is earning money, and it, or some other pump, is essential to enable the owner to operate the business. Manifestly, to take the pump away from him without paying for it would entail a loss to him. He admits that he could earn more by buying a new pump, but he has put so much capital into the development of the business, that he does not wish to invest more money at present. The money spent in development has been wisely expended, because the net earnings are now nearly enough to pay a reasonable return on all that he has invested in the water-works, and the net earnings are growing so rapidly as to promise in a few years a profit on the investment, when he will be in position to secure plenty of additional capital for improvements, etc. Now, the city does not contemplate buying from him just the pump

Mr. Dana.

alone, at a negative valuation. It has an option on the whole plant of which the pump is but one part, and he stands no loss if he receives a negative value on the pump, provided he gets a proper positive value in the form of Development Expense. If it should appear that he has received a fair return in dividends and interest on the capital invested to date, operating expenses to include depreciation, then there is no Development Expense, and the pump no longer represents to him a capital investment equivalent to its original cost.

In calculating the Development Expense proper depreciation charges should be considered a part of operating expenses, in arriving at the correct amount of net earnings. On that basis, and that basis alone, can the Development Expense be correctly figured, and then it is logical, consistent, and proper to allow to the items of plant their true functional value, which may be, and often is, negative. Where this practice is omitted, injustice is sure to be done. When properly applied, it affords the owner ample protection against actual loss, and, at the same time, enables the community to acquire the plant or fix the rates on a basis no higher than would have been the case had the community built and developed the plant in the same manner and at the same time that the owner actually did develop it. Moreover, as the development by the owner is likely to have been more economical and efficient than if it had been done by the community, there is a greater or less intangible profit accruing to the latter if the owner is allowed only the exact amount represented by his investment. To regard the owner as having been in effect the agent of the community in developing the property, besides being fair to the owner, is not unfair to the community. On this criterion is based the so-called "Agency Theory" of valuation.

Very frequently, and nearly always in the case of railways, it occurs that competitive rates are such and development expense has been so heavy that the owner is not receiving a normal rate of return on his capital, nor can he perceive such a return in sight. He, therefore, would be glad to sell his property for less than the "fair value", taking a loss in order to go into a more profitable business. If the community can ascertain what this amount is by bargain, then a purchase at that price may be effected, but obviously it would be the height of injustice to regulate rates so as to cut down the net return below a normal rate on the owner's capital in order to coerce him into selling at a loss. By the same token, his point of view of value is that which should be taken in fixing rates.

Aside from these reasons for using original rather than present unit prices in computing plant value, there are occasional difficulties in the practical application of the present-unit-price method. For instance, in Central New York State a good many piles, driven 50 or 60 years ago, are of the most magnificent white oak, with butts of

22 in. and more. There is no market for that kind of material at present in that part of the country, and freight from a long distance would make the unit prices on such material prohibitive to-day. To apply present unit prices then on such material is virtually impossible, except by assuming that the owner should be contented with the unit price on something else "just as good". Consider the matter of ashlar masonry laid in Portland cement mortar when the cement cost $4 per bbl. To-day, the same function would be performed by concrete made with cement costing less than half that price. To allow the owner present prices on concrete and calculate his masonry in that manner, in fixing rates, would compel him to stand a very considerable loss. It cannot be objected that he must stand that depreciation anyway, because the original cost of the ashlar with the high priced cement must be depreciated to get the present (to him) value, as outlined. To allow present prices of cement and calculate the present reproduction cost of ashlar, would force him to take an unfair loss on the cement, and so little ashlar masonry is built in these days that there is hardly a free market price for it. It is in a class with the large oak piles previously mentioned. Mr. Dana.

The writer understands from the report (page 15) that it is the opinion of the Committee that though present prices should be used, the estimated cost should be based on the conditions existing at the time of construction. As prevailing prices are among the conditions of construction, the Committee's ruling seems to the writer to lack consistency, especially as

"The Committee believes it to be a general basic principle that where money has been expended with due discretion * * *, the company is, in the case of a newly erected normal property, entitled to a fair return upon a value which, subject to modifications, equals the amount of money invested."

With the last paragraph under "Unit Prices" (page 20), the writer cannot agree. In the case of lumber, as quoted for illustration in the report, the prices have been rising, and probably will continue to do so in the East, until the Panama Canal is finished, when they will go lower in the East and higher in the Far West. Can the building of the Panama Canal afford an excuse for cutting the rates charged by a railroad in Pennsylvania, which has been able to earn just enough to pay interest on its actual capital investment, with depreciation on plant which includes many timber trestles? To depend on the appraiser "to select the length of the period with a view to obtaining a fair prevailing price" does not seem logical or practical in its application. The writer ventures to call attention to the fact that, in the vast majority of cases, the aggregate depreciation is much more than the aggregate appreciation on physical property, and that this fact is likely to militate against the fair interest of the owner, unless a correct

Mr. Dana.

amount for Development Expense be allowed. Now, this line of reasoning assumes that there is a positive "Development Expense", and is consistent with the "Agency Theory" of valuation, to which four very important objections (among others), have been made, *viz.*:

(1) That the owner never was an agent and, therefore, should not be considered as such;

(2) That the owner is entitled to appreciation in value, in such items, for instance, as real estate, arising from the development of the community in which his property is located; and that the theory outlined does not allow him such profits;

(3) That when the rate of allowable return is taken from the standpoint of the owner, the community is overcharged, because it could have obtained the money at much lower rates than the "fair-return" rate to the owner;

(4) That the Agency Theory eliminates Franchise Value.

(1) The first of these objections, which has been made in legal proceedings, is somewhat overstated. Had the owner actually been appointed agent for the community, the latter would have to stand for all his blunders, except where intent to defraud was demonstrable. Frequently, the community treats the owner as anything but its agent, as in the case of Seattle, Wash., holding down his rates by commissions and competing with him by a municipally owned plant. Whether or not the owner actually was an agent seems to be beside the issue, except on the basis of a purely legal technicality, which need not concern us here. The Agency Theory has been thus called because the term conveniently expresses a logical hypothesis which, in its proper application, protects the owner against actual loss, except by blunders, as though he were the community's agent.

(2) The second objection is of much importance. There are cases in which development expense has been extinguished by surplus earnings, although this is rare indeed in the railroad business.

Where the land can be sold and the profit gained without interfering with the business as an operating entity, it seems that the owner is entitled to the profit, as before discussed. In regard to the property which is an integral part of the business, the Courts have ruled that the owner is entitled to appreciation, he is taxed on the appreciated value, and if he be not allowed to earn a return on the appreciated value, what justification is there in making him take a loss on property which has been lost or has depreciated, such as an abandoned piece of track?

Were a possible competitior to appear and attempt to buy the owner out, there is little doubt that the competitor would expect to pay about the present value of the land. If he succeeded in getting it for less, he would consider it a fine bargain. If he had to pay much more he

would buy elsewhere, or give up the idea. Now, the community, under the common-law theory of individual right, has no right to compel the owner to take less for his land than a competitor would expect to pay. If there is other land available, the community can buy the other land and allow the owner to use his land in some other business or otherwise dispose of it. It might not want to do this, because of the expense of moving tracks and buildings to another site, but that is no reason for not giving the owner his profit, if he is going to be forced out of business. In such a case as that of the New York Central Terminal on Manhattan Island, there is no other available site for the purpose, but here the owner must be entitled to a value based on the assumption that he may proceed to enjoy equally desirable land if he should want to go into some other business or otherwise dispose of his land, turning over the old business to the community. For rate-making purposes, the rates must be adjusted on the assumption that the owner would fare as well as if the community bought the property on the fair valuation. Any other view than the one stated will make the owner wish that he had used his property in some other business, one in which the community would have left him in peace to enjoy his prosperity. Emphasis should be laid on the fact that the "greatest good to the greatest number" is consistent with placing a premium, rather than a discount, on the use of private capital for public purposes. Any other view means socialism, if not anarchy. Mr. Dana.

(3) In regard to the third objection, the writer believes that if the owner put in his own capital, he has a right to the same return on it as if he put it into another business. The community might have borrowed it for less, but it did not, and as it had its choice in the matter and the owner did not, he is entitled to the normal rate of return on private capital.

(4) The fourth objection has certain intrinsic features in common with the second, and furnishes a clue to its solution.

If the owner is to be paid rates which will just allow him to earn a fair return on his investment, and there is no prospect of his being able, or allowed, to earn more than this in the future, of what good is a franchise to him? The original and only idea of a franchise or charter has always been to induce him to apply his money to public purposes rather than to use it in some other form of industry. Now that the State has money of its own, it seems hardly equitable to penalize the owner because he allowed himself to be persuaded to invest it under the inducement of a franchise or charter. Where there has been expense of development, which has not been amortized out of net earnings, and is not likely to be, there is no "franchise value" anyway, and the "franchise" simply amounts to a contract on the part of the community to let him stay in business and try to make up his losses. Where there is no accrued development expense a franchise

Mr. Dana. is a public bonus, in the form of a contract, whereby the owner may expect to earn an extra return on his capital as an inducement not to go elsewhere with it.

These four objections to the Agency Theory are based on what has been termed the Competitive Theory, which sometimes gives a total appraisement higher than the Agency Theory, and sometimes lower. In general, where there is a considerable Development Expense, the Competitive Theory gives a lower total than the Agency Theory.

It is often necessary in an individual problem to make two or more valuations, one on the Agency Theory, and another on the Competitive Theory, in which case the totals will not agree. It is certainly illogical to make a computation of value, some of the elements of which are calculated on the one theory and the others on the other.

Mr. McCormick. R. S. McCormick, M. Am. Soc. C. E. (by letter).—The Committee has presented a very able and exhaustive report, and it will doubtless be received as expressing the Society's stand on this subject.

The writer, however, desires to call attention to the fact that, in his opinion, the Society cannot afford to go on record in this way, and although the Committee has stated that the report is incomplete, and doubtless discussion will bring out points not touched on, he feels that it would have been more consistent with the object and aim of the Society to have confined the report to the question of valuation alone, omitting the application of such valuation, at least, to the extent of applying the whole argument to this purpose. The report might have been treated as an abstract subject of valuation, with and without depreciation.

There is a difference between the valuation of railroad property and other kinds of public utility property for rate-making purposes. Competition is not dead in the industrial world, not even as between large combinations, and although this competition is of a different kind from the old sort, it is not the less real, and its effect on the fixing of rates is a live issue between traffic managers on railroad systems. Where this kind of competition is possible, the matter of rates will never be wholly, or probably in any great measure, based on the principle of a fair return on the value of the property. This principle, however, is equitable, and, where it is possible to apply it, will give equitable returns. In the case of public utilities such as water-works, street railways, gas and lighting plants, etc., it is possible so to base rates. In the writer's opinion, however, it is wholly impracticable to apply this principle in this way to 95% of the railroad mileage of the United States; and, to say that these properties are valued for rate-making purposes is a misnomer.

The valuation of railroad properties, no matter how made, or on what principles as regards the question of depreciation, can be useful

Mr. McCormick.

only as a guide to prevent exorbitant rates, and can never prevent lower rates than will give a fair return on the investment.

In the case of local public utilities, on the other hand, this valuation can be the fixed base for rate-making, because, speaking generally, there is no competition. For this purpose only a discussion on valuation for rate-making is properly applicable.

To value properly any one of the great railroad systems involves a most intricate and exhaustive examination by men properly qualified, and to know when an equitable value has been given to the properties is well worthy of the best efforts of those engaged in the work.

When all the data are collected and reported to the Commission, and a value is placed on the multitudinous items comprising this inventory, its value for rate-making purposes can be a fit subject for discussion.

The writer is of the opinion that such a valuation should be for the sole purpose of ascertaining the worth of the properties as property, keeping in mind the use to which it is put, and should have no bearing as to the purpose for which the valuation is made. This value may be present value, original cost of property to date, or a value based on cost of reproduction with or without depreciation. The various differences of opinion as to which method will give the true value presents a sufficient field for discussion without including the purpose for which it is to be made. It is unwise to go at this subject with any other object in view. This is especially applicable to railroad property, and the Interstate Commerce Commission has begun this work under a most serious handicap because the railway companies are getting a wrong impression in regard to its object.

It will not be possible to carry on this work and do justice to the carriers unless the engineers of the Commission and the companies' engineers agree on a common basis regarding values. To hamper either side with the burden of reconciling these values for any particular purpose is essentially wrong in principle, and, at least, should not be a subject for discussion until the inventory of the properties is complete and the value fixed by the Commission under the terms of the Act. Section 19-*a* certainly is explicit as defining what the Commission is to do, and it does not say that this valuation is to be made for the purpose of rate-making.

Although it is understood that such at least is one of the objects of the valuation—perhaps the principal one—the Commission has no authority to make this valuation with this end in view, and hence the Committee's report should have dealt with the subject in a broader sense, or, if this purpose—rate-making—was the object, it should have recognized the distinction between public utilities of the class where absolutely no competition is possible, and those where it is possible. This competition, although perhaps not fixing the rate, has, in a

Mr. McCormick.

broad sense, much more to do with it than the actual value of the property could ever have. The physical value is of great assistance in adjusting rates, but not in making them.

Mr. McCarty.

RICHARD J. MCCARTY, M. AM. SOC. C. E. (by letter).—Realizing the importance of light on valuation of public utilities, the Board of Direction in October, 1911, appointed a Committee to investigate and report on the subject. At that time the full significance of the problem had not been developed, and it was generally regarded as one to be solved in the main by the Engineering Profession.

To judge from its Progress Report, the Committee addressed itself to the task with the utmost energy, and did great credit both to itself and to the Society by the public spirit manifested.

The passage of the Federal Valuation Act, and its approval on March 1st, 1913, made the problem one of national importance, and caused its fundamental significance to be investigated by many who before that time had given it particular attention only as applied to special cases.

A thorough consideration of the general character of the problem shows that its ultimate solution must be reached from the standpoint of Economics, Law, and Equity, rather than of Engineering. That the Committee realized this is shown by the following quotation from its report:

"The principles and methods involved are now being carefully considered by many public service commissions and the Courts, as well as by engineers, lawyers, and committees of various societies having to do with public utilities. The subject is clearly in the developmental stage, and any conclusions reached at the present time must be considered as tentative."

The Committee then states that:

"It is recognized, however, that the whole subject is in a developmental stage, and while your Committee has been guided largely by the decisions of the higher Courts and public service commissions, it recommends what seem to be sound views and desirable changes in practice, even though not wholly in accord with such decisions."

It is not here held that the problem of valuation does not call for the highest type of engineering ability, but it is held that the work of the engineer terminates at the point at which the quantities and values for use of the different parts of the physical property of any given public utility shall have been determined, and that from this point forward the problem ceases to have particular significance to him. The reason for this is that the determination of the value for use of physical parts of a public utility, and the application of such values in determining the amount of capital on which a public service corporation is entitled to a fair rate of return, are problems of an

Mr. McCarty.

entirely different character, and belong to entirely different departments of human thought and experience.

This is recognized in the Federal Valuation Act itself, which requires that there shall be ascertained and reported the original cost to date, cost of reproduction new, cost of reproduction less depreciation, other values, elements of value, and, separately from improvements, the original cost and present value of lands, rights of way, and terminals. The Act, however, is so far from stating the manner in which this information shall be applied, that it does not even give the purpose for which it is to be used.

The manifest intention of the Act is to obtain certain information through the Engineering Profession concerning the physical features of public service utilities, and to use the results thus obtained as a basis for determining the amount of capital on which the owner is entitled to a fair rate of return, and for other proper purposes.

For the American Society of Civil Engineers to investigate and give to the Engineering Profession information and data concerning the determination of the value for use of the physical parts of public utilities is eminently fit and proper, but for it to go beyond that point would be an invasion by the Society of the respective provinces of Law, Equity, and Economics.

This, the writer is convinced, the Society cannot afford to do, either in justice to itself, as the leading engineering organization of the United States, or in justice to the public, which heretofore it has benefited to such a great extent.

The effect of an attempt by the Society to solve problems of Law, Equity, and Economics would be great, because of the great influence on the Governmental authorities, and on the Courts, of any conclusions which it might reach or apparently endorse, and inasmuch as the Committee itself had recognized that any conclusions reached at the present time must be considered as tentative, it naturally follows that such conclusions should not be advanced under the auspices of the American Society of Civil Engineers.

The writer, therefore, is of the opinion that the report of the Committee should be confined strictly to the determination of the value for use of the physical parts of public utilities, and should not make any recommendations, or advance any tentative conclusions, concerning the manner in which the results of such determination shall be applied to questions arising between the owner of the utility on the one hand and the public on the other.

It seems particularly important that the Society, as well as the Committee, should adopt this course, because, it might easily happen that, owing to the influence of the former, and the standing and reputation of the members of the Committee, certain tentative conclusions might be embodied in the decisions of the highest Courts, which after-

Mr. McCarty.

ward might be shown to be untenable, and thus work great injustice either to the public or to the owner of the public utility.

Mr. Buel.

A. W. BUEL, M. AM. SOC. C. E. (by letter).—Has the Committee considered what items should be covered by a "fair return"? If it covers risk of investment, why not also risk of development expenses or deferred dividends? It is necessary to answer these questions, in order to avoid duplicating the same items in the valuation and in the fair return. Is there a method by which a "fair return" may be determined from statistics? Although the final answer to these questions will have to depend on decisions of the Courts, it is the duty of valuation engineers to collect and present all data relative to the discussion.

Losing ventures would probably occur as often, if not oftener, under public ownership, and, therefore, they should be given some consideration. They may be divided into two classes with such approximation as can be ascertained by the historical facts. First, those which at their inception appeared to offer fair hopes of becoming profitable within a reasonable time, such as would attract conservative capitalists, but which failed to develop as anticipated; and, second, those which, at the time they were promoted, would not have appealed to prudent men as reasonable business risks. If the second class be eliminated, and the first class of losing ventures be combined with more or less profitable properties of the same kind, similarly conditioned, the expenditures for capital account and the net earnings or operating incomes for a series of years, for the entire group, should furnish a basis for determining the percentage of risk involved.

All the capital invested in the group, less the capital losses divided by the capital invested, gives the percentage of security. If a fair return, where no risk of loss is involved, is assumed at 4%, to compensate for the risk of loss of capital, it must be increased to the percentage that 4 would be on the percentage of security. Thus, if an average of 20% of capital invested in railway construction were lost, the percentage of security would be 80, and 4 divided by 80 is 5%, the return required to compensate for the capital risk.

To find the "fair return", however, we must also add compensation for lost and deferred dividends, unless these have been added to the cost of the properties in the valuations as development expenses. It would seem preferable to take care of these items as elements of risk in fixing fair returns, rather than to add them to cost of property as development expense, because they may vary greatly in the same territory and on competing lines which, both on the ground of equity and of the practical difficulties involved, require equal treatment on the common basis of the average return on the total capital investment in the group plus lost or deferred dividends, excluding losing ventures of the second class. It seems quite as logical to treat them as risks

Mr. Buel.

or losses as to consider them as development expense added to valuation costs. This method also has the advantage of greater clearness in segregating the values of purely physical property, thus reducing complications in arriving at operating values or valuations as going concerns, or, as some call it, good-will.

If we add all lost dividends, compounded at 4%, up to the average age of operating maturity, at which profitable properties begin to earn fair returns, to the capital invested in the group, then 4% on this sum divided by the percentage of security gives the fair return for this group.

Assuming 10 years for the age of maturity, for example, a percentage of security at 80 as before, also that the 20% of losing ventures of the first class just earn operating expenses and taxes on the average, and that the average earnings of the 80% of paying properties during the first 10 years is 2% less than a fair return, we have:

Lost dividends on 20% of losing ventures, compounded at 4% for 10 years, amount to 20% of 48.02%, or.....	9.6%
Lost dividends on 80% of paying properties during 10 years of development at 2% compounded at 4% amount to 80% of 24.01%, or.....	19.2%
Total lost in dividends.....	28.8%
Original investment in group.....	100.0%
Total " " "	128.8%

Four per cent. on 128.8% is 5.152%, which divided by 80 gives 6.44% as the fair return that insures an average yield of 4% on the investment. If this group represents four competing railway lines, the average return of 6.44% might be made up of 2% on the investment in one line, 10% on another line, and intermediate rates on the other two.

Of course, it is understood that these figures are merely assumed for an example, but it ought not to be impracticable to derive fairly close percentages for the losing ventures and lost dividends from a careful analysis of the records of large groups of kindred properties. It would probably be necessary to fix some limit on the age of maturity.

If the percentage of security is 90 and the lost dividends compounded at 4% amount to only 14.4%, then the fair return would only be 5.08 per cent. Of this, 4% may be called interest on investment and 1.08% insurance of capital and interest.

Though the Committee recognizes the equity of some recognition of operating values, or, to use its term, "efficiency", as a "modification of the physical valuation or of the rate of return upon such valuation", it in effect puts this problem up to the commissions

Mr. Buel.

and the Courts. Without question, some points involved in this element of valuation will have to await Court decisions for final determination; but, on the other hand, the larger part of this problem consists of highly technical matters which will devolve on engineers to solve. In fact, the determination of operating values or efficiency seems to be more especially an engineering problem than one of depreciation, which is largely a matter of accounting, or of inventory valuation of the real estate and many other elements of the physical property. The Committee's report suggests, quite correctly, the great difficulty of formulating any general rules for the practical application of this feature, but, because of its importance and the fact that it is generally so little understood, it deserves particular attention.

This problem of efficiency or operating values is so complex that it is extremely doubtful if it will be possible to lay down any formulas or rules except those of the most general character. Possibly, the only practical method will be found to consist in making comparative estimates of operating values of the existing property and of an ideal or hypothetical equivalent on some revised location or design, which involves surveys for revisions or new designs. But intelligent reconnaissance work will confine the extent of such investigations to practical limits. This method is not only feasible for determining operating values of railways and other properties with sufficient accuracy for all practical purposes, but it can also be used to advantage in estimating the efficiency of operating methods. Estimates of operating values and operating costs should be made in full detail, treating each variable item of cost separately for each varying condition. This is laborious and voluminous, but, for many cases, it is the only convincing method which as yet has been suggested. The writer has used it in studies of several thousand miles of railway locations and revisions under widely varying conditions, and it has always proved satisfactory. The degree of accuracy that may be attained by this method depends principally on the care used in finding correct data, particularly of the unit costs, and the formulas by which they vary. The latter, of course, can only be arbitrary approximations in most cases, but, if the data are based on broad averages taken from statistics of actual operations of properties working under as nearly similar conditions as possible, the final results will be substantially correct. No good would result from attempting a greater degree of accuracy than the variation of one normal year or another from the average, and the method suggested can be made to approach this if care is taken and good judgment used.

As the efficiency of any plant, location, or design depends to the greatest extent on its proper adaptation to the volume of business handled, it would be decidedly unfair to leave out of consideration the volume of business in sight, or that could have been reasonably

foreseen, at the time the property was constructed. The volume of business may have increased to such an extent that the original property or parts of it are practically obsolete, requiring reconstruction, revisions, and new facilities. No doubt many questions will arise as to just what is the equitable way to handle such cases of insufficiency of plant, but the circumstances and conditions may be so variable that a general rule could not be formulated to cover them. They probably belong in the class calling for the use of the best professional judgment available, except where they may be covered by Court decisions. Mr. Buel.

In another class are a few cases in which expensive revisions or reconstruction have been undertaken, entirely unwarranted by the volume of business in sight. For example, a railway with comparatively light traffic may have spent many millions of dollars in revisions to reduce mountain grades, without cutting down the summit elevation and at the expense of considerably increasing the distance, the savings in operating costs, being entirely inadequate to pay the interest on the additional investment. While, in time, the traffic may grow to a volume warranting the revision, if the expectation of such a result is deferred to an unreasonable time the revision should have been deferred. In such a case it is questionable what, if anything, should be allowed in the valuation for the cost of the revision. Though such cases are probably rare, some will be met. The example suggested serves to bring out by contrast the more numerous classes of poor original location or design and of those which have become obsolete and inadequate due to the growth of traffic, all of which suggest the large number of important and difficult questions in valuation still remaining to be solved.

J. E. WILLOUGHBY, M. AM. SOC. C. E. (by letter).—The subject under investigation of the Committee was worded so as to give prominence to "railroad property". It seems unfortunate that the report draws its illustrations principally from, and is pervaded with ideas relating to, water-works and sewerage plants. It is possible that the treatment would have been somewhat different had the underlying idea of the Committee been the valuation of railroad property. The writer's experience is confined to the construction, maintenance, and valuation of railroad property, and the comments hereinafter made are formed from experience with railroad property only. Mr. Willoughby.

The writer is not in sympathy with the formulation of principles and methods of valuation for rate-making, as distinguished from any other purposes. Whenever such a distinction is made, the presumption is raised that a valuation for rate-making purposes differs from, and is higher than, a valuation made as the basis of a sale. Such a presumption is unjust to the owner. The items which enter into the valuation covered by the Committee's report appertain almost exclusively to the determination of the cost (either original or replace-

Mr. Willoughby.

ment) of the physical property, and a valuation confined solely to the cost of the physical property is unjust to the owner. For example, take good-will. In a water-works monopoly, good will may be of but small value, but in a railway property it is often that which makes one railroad prosper, while the competing railway goes into bankruptcy. Inasmuch as the valuation of a public utility property includes other items than the cost of the physical property, the Committee's report is incomplete, and in that form it prevents the assignment of losses due to use (*e. g.*, depreciation) to the proper place in the valuation.

General Principles Involved in Valuation for Rate-Making.—As a corollary to the first of the two features suggested by the Committee as to the requirements of justice in any regulation of rates (page 7), the writer suggests that the annual return, in addition to covering interest and profit for the use of the capital, should provide such earnings as will enable the owner to meet the demands of the public through its public service commissions for additions to the property which cannot be capitalized without affecting the general credit of the owner. A familiar example of this kind of additions is found in the rivalry of the cities, and even towns, for union stations, monumental in character, and costing out of all proportion to the economic saving in transportation.

Fair Value for Rate-Making.—The fair value for rate-making for railway properties should consider the whole territory served by the properties. Rates that are not sufficiently high to provide an adequate return for some lines within a territory would for other lines in that territory, which enjoy a less capital expenditure and less operating cost, produce more than what is usually considered as a reasonable return. The Committee's report considers the abnormal case of a property which must be a losing venture, but overlooks the abnormal case of a property which must be a sort of El Dorado.

Methods of Determining Physical Value.—The writer is in accord with the Committee in its conclusions that a valuation of an old property must necessarily be made after the cost-of-reproduction method; and that the identical plant is to be reproduced and not a substitute plant. These conclusions are particularly true with regard to railway properties. If the cost of substitute railways were proposed, the actual locations on the surface of the earth of the existing railway under investigation, the rates of grade, and curvature, etc., with all the theories of economic operation, would be a subject of inquiry, the end of which would be confusion. Furthermore, reproduction of the identical railway prohibits the process of inquiry from theoretically correcting errors of location and construction, which often become apparent after the completion of the railway. This is just to the owner. Errors of location and construction are an inevitable consequence of railway construction, and the burdens of such rest on the public. The

Mr. Willoughby.

burden of an error of the owner in constructing a railway for which there is no economic necessity properly rests on the owner, except in those communities where the public through its laws and commissions, exercises the right of authorizing or denying the construction of any proposed railway.

Present, or Original, Conditions.—The conclusion of the Committee, that "the valuation should be based on the conditions existing at the time the various portions of the property were built, but on prices prevailing at or near the time of valuation", will result in confusion if applied to railway properties. Railway construction requires that there shall be the necessary materials of construction, machinery, teams, and tools of their several kinds, labor, skilled and unskilled, and transportation. The costs of construction work have a direct relation to all these items. When they are readily obtainable and cheap, the cost of the work is small; any scarcity of either causes the unit prices to advance. Some materials that were available (*e. g.*, cheap timber) when many of our railways were built, no longer exist; other materials (*e. g.*, cheap steel, explosives, and cements) were not then obtainable. As a result, many features of construction now called temporary were then adopted. It would be unjust to the public to capitalize in a present-day cost-of-reproduction valuation the trestles that were built long years ago and afterward filled, for a railway in a community where such methods are not at this day habitually practised as an economy. The convenience of transportation facilities to the railway subject to the valuation, affects enormously the unit costs of the work. The transportation conditions at the time of original construction, generally, were such that we cannot intelligently modify the unit costs attainable with modern excavating machinery to fit the original conditions, and we get unit prices and construction periods that are unreasonable. The difficulties recited by the Committee as making undesirable the use of present-day conditions are easier to overcome in railway valuations than the new difficulties that arise if we undertake to revive the original conditions. Take the Wachusett Reservoir. With present-day conditions, we would assume in case a highway or railway reaches one limit of the reservoir property, follows partly around the reservoir property and departs from it, that the highway or railway crossed the reservoir property, and was reconstructed on its present location, the cost-of-reproduction of which would be determined in accord with the principles and methods under discussion by the Society. An examination by borings would determine if the original soil were stripped from the reservoir site; and an examination of the depth of soil beyond the limits of the wetted area would determine the estimated depth of surface soil removed. The damages paid to the adjoining real estate, as incident to construction, would be estimated in accord with the experience of the inquiry as against all

Mr. Willoughby.

real estate in the condition of improvement which that real estate exhibited at the date of the inquiry. If, at the date of the inquiry, there were buildings on all sides of the reservoir property, the assumption would lie that like buildings would extend over the whole reservoir site; if buildings were about a portion only of the reservoir property, the higher value of the improved real estate would attach to that proportion of the area of the reservoir which the improved portion bears to the whole perimeter of the reservoir site. Such a method would give to the owner the benefit of the decision of the Federal Supreme Court in the Minnesota rate case, and some part of the increment in the value of the property that is the just due of the owner. Take the illustration given of the New York Central Station. It is equity to assume that the old station was obsolete, and that its original cost had been returned to the owner through earnings during its life, and that a new station of the character provided was necessary for present use and the reasonable requirements of the future. To make a valuation after the cost-of-reproduction method, the assumption is made that all improvements on the station site are obliterated. If the inquiry is made, at the same time, of the cost-of-reproduction of the railways which are using the station, no injustice is done the owner, because there is no traffic to handle. If the inquiry is made as to the cost-of-reproduction of the station only, then the inquiry must make provision for the traffic, either by providing as a part of the cost of the new station other property for temporary use with temporary facilities, or by so augmenting the unit costs of the construction work as to permit the work to be undertaken with all the burdens of handling the traffic existing at the date of the inquiry. The burdens on the work, as a consequence of the proximity of other properties, rights and interests at the date of the inquiry, would rest in either case.

Application of Reproduction Method of Valuation.—The conclusion of the Committee, that "it is necessary to make a deduction from the values obtained * * * for the net accrued depreciation of the physical property due to age and other causes" does not necessarily follow for railway properties. Depreciation is merely an item of maintenance of some part of the plant deferred beyond the period of one year because the nature of that part does not permit the repair to be made within one year. If our accounting were in ten-year periods, instead of one-year periods, many of the items to be provided for as depreciation, and to be deducted from the value of the physical property under the Committee's conclusion, would be considered as items of maintenance, and, therefore, not deducted from the value of the physical property. The difficulty may be overcome by regarding depreciation as a deferred maintenance, to be taken into the annual accounting as a liability of the owner, but not to be deducted from the value of the physical property for rate-making purposes, or for

Mr. Willoughby.

any other purpose, any more than any other liability is to be deducted from the value of the physical property, for illustration, the unpaid fuel bills. Being an item of indebtedness of the owner, the accrued depreciation at the end of any fiscal year should be accurately set out in the accounting so that the amount thereof would be a debit against the assets of the owner. The assets of the owner will include items in addition to the physical property of the plant, and it is unjust to the owner to reduce the value of his physical property by a liability necessarily incurred in the operation of the plant, and which his balance sheet shows to be within his ability to meet when the necessity arises, and then on such reduced valuation, to fix the rates to be charged for service, or to fix the amount of a purchase price.

Inventory.—The writer would add, to the Committee's illustrations, the familiar one of the depression of the underlying soil by the weight of railway embankments when constructed over the low-lying lands of the Coastal Plain in the South Atlantic and Gulf States, and on similar soils elsewhere. The amount of this subsidence is not determinable from any measurements, made after completion of the roadway, of the volume of the embankment, although the amount of such subsidence is often 20% and more of the total volume of the embankment.

Unit Prices.—Care must be taken in adapting present-day prices to the cost-of-reproduction method. The present-day prices most naturally chosen will be those current, on the work of the railway under inquiry, for additions and betterments, in connection with like prices on railways in the same general territory. Now, such prices are always based on facilities of transportation afforded by the railway to which the inquiry of cost-of-reproduction is directed, and on other concessions in the way of free transportation, etc. Proper additions should be made to such current prices to ascertain what would be the correct unit prices, were the railway and its branches assumed as being blotted out preparatory to its reproduction under present-day conditions.

Another feature having an enormous effect on unit prices is the demand made at any one time on the plants, organizations, and labor available for railway construction. In order that the assumptions necessary for a cost-of-reproduction may not become absurd, the amount of work proposed to be done, and the time limits set therefor, must be in reasonable accord with the available agencies for construction, all other business being assumed to be normal. This requirement can best be met for the larger systems by assuming that the reproduction work in any one State is undertaken separately from that of any other State, and that the construction agencies of all adjoining States are available. This assumption would fix as a maximum time limit the time necessary to reproduce that portion of the railway system under inquiry which exists in one State only. The suggestion of divi-

Mr. Willoughby.

sion into States grows out of the probability that the results of the cost-of-reproduction valuation will be required for use in intra-state discussions as well as in interstate discussions.

The following assumptions may be made in endeavoring to adapt present-day prices in the older parts of the United States to the method of cost-of-reproduction:

1.—That the work will be done under all the present-day conditions; with the available contractors, and with labor of its present amount and efficiency, and with machinery of the several kinds now in daily use; and that the contract of the work will be burdened with all the prejudices, legal hostilities, and greeds held by the public against railway enterprises, which enable the contractors and the public to collect doubtful and unjust claims against the railway company.

2.—That the railway is to be built exactly as it exists at the time the estimate is made (even to repeating all the engineering errors that appear in the existing railway), and that the better railway, in the light of present-day needs, which might be built for the same money is not to be reproduced.

3.—That the railway to be reproduced must be considered as being entirely obliterated; the right of way re-afforested where any growing timber now touches either limit of the right of way, and as swamp land where swamp lands now border the right of way; as fields or meadows when such border the right of way, and as city or town lots for the length the railway exists within the limits of cities and towns. All cuts are to be considered as re-filled, and all embankments and structures of every kind as being entirely removed. These conditions are necessary to enable an estimate to be made of the amount of work to be done.

4.—That with the obliteration of the railway, the facilities of transportation afforded by the railway itself, or its branches no longer are available. There is a definite and determinable relation between the cost of the construction of the roadway, and structures of a railway, and the distances over which material, labor, and supplies must be transported by wagon haul.

5.—That all the facilities of transportation offered by rail lines other than the line to be reproduced, and by all water lines and highways, adjoining the line to be reproduced, are available at the current transportation rates and conditions.

6.—That when a system extending over many States is to be reproduced, it will be advisable to consider the work as being done in certain sections or zones, and to estimate the work of reproduction of each section or zone separately. This assumption is important because it is physically impracticable to construct the whole of an extensive system at one operation, without introducing fabulously high

construction costs, due to the lack of labor and appliances for such construction, when other business is normal in the United States.

7.—That the natural divisions into sections and zones will be by States. In any event, it will be necessary to tabulate the reproduction cost of work by States, and when it becomes necessary to use the reproduction cost in intra-state matters, any item of reproduction cost of the lines within the State that is affected by the assumption of the obliteration of lines without the State cannot be defended in a controversy over intra-state matters.

8.—That within any one State the main lines (both principal and secondary) should first be reproduced, and then the branch lines and spurs. Such an assumption will lessen the construction cost of the branch lines and spurs, because of the transportation facilities afforded by the main lines.

9.—That the time element is of great value, more than the mere calculation of interest on monies expended.

The purpose of these several assumptions is to make clear the conditions to be considered in determining the correct quantities and correct unit costs to be used in the calculations for cost-of-reproduction.

With particular reference to the lines composing the railway systems in the Atlantic Coastal Plain, Fig. 6, the varying character of the soils, native resources, transportation facilities, etc., forbid the adoption of a single unit price for the several items of railway construction, for the system as a whole, or even for all the lines in one State; for example, the dry soils of Florida are generally too soft and too light to permit the economical use of scraper outfits, and the wet soils are too swampy. This condition makes necessary the use of human labor. The dry soils of Southwest Georgia and South Alabama are generally indurated to such an extent as to be too hard for the economical use of scraper outfits, and at the same time, the transportation facilities are too meager to permit the bringing of steam excavating machinery and fuel therefor. This results in high unit costs, due to the use of scraper outfits and human labor on materials not economically adapted for such.

The unit costs for branch lines should generally be taken as less than for the main lines, to be in accord with the eighth assumption, and because the time element is not of such value as in the completion of main lines.

The fixing of unit costs can be arrived at by considering separately each strip of 50 to 100 miles of railway, and fixing unit prices for each strip, which (if there be any desire therefor) may be then averaged for the State as a whole.

As an example, consider the unit cost of grading required for the reproduction of the main line of the Atlantic Coast Line Railroad from the Virginia State line to Wilson, 62 miles. The single-track railway was

Mr. Willoughby.

built more than 50 years ago. It has been constantly improved until it is now a double-track main line of the first class, carrying heavy and fast traffic. If the main line and branches are assumed to be obliterated there would remain the following rail and water transportation facilities: Atlantic Coast Line at Virginia State Line, Seaboard Air Line at Weldon, Norfolk-Southern at Wilson, Roanoke River at Weldon, Eastern Carolina from Tarboro south.

The present-day contract unit prices paid by the Coast Line in this territory are confined exclusively to construction of second tracks and other additions to the property. These unit prices were based on the privilege of free transportation of men and materials, etc., over an extensive mileage, and, to adapt them to the cost-of-reproduction method, with no free transportation, and none of any kind during the reproduction period, by that portion of the railway under inquiry, there should be added the following percentages:

1.—The value to the contractor of the free transportation over the Coast Line on employees, tools, machinery, construction material, and fuel for steam shovels, etc., in percentage of the contract price.....10%

2.—The additional cost of construction on account of transporting men and animals, tools, machinery and supplies overland, from the nearest transportation facilities for distances in excess of an average wagon haul of 5 miles; to-wit: 16½ miles at 10% increase for each 5 miles $= 16.5 \times \frac{10}{5} = 33$ per cent. The 33%, however, applies only to the strip from Wilson to Weldon (85% of length Virginia State Line to Wilson), because there are transportation facilities within 5 miles of that portion of the main line between Virginia State line and Weldon, 33% of 85% =.....28%

3.—The additional cost of construction due to the payment of higher wages to labor, necessary to induce labor to go to and remain on the line from Wilson to Weldon, remote from transportation facilities: 20% of 53% of length of line affected = 10.6 per cent. Inasmuch as the labor cost is only about one-half the total construction cost, the total increase in percentage becomes.....5%

4.—The additional construction cost due to increases in prices resulting from the demands made on the labor and material markets of North Carolina were the 553 miles of principal and secondary main line of the Atlantic Coast Line to be reproduced as a single operation: 25% on 50% of total, in percentage.....12%

5.—The additional sum necessary to be procured by the contractor as profits to warrant him in handling the greater amount of capital: 5% of 55%.....3%

Total increase.....58%

Mr. Willoughby.

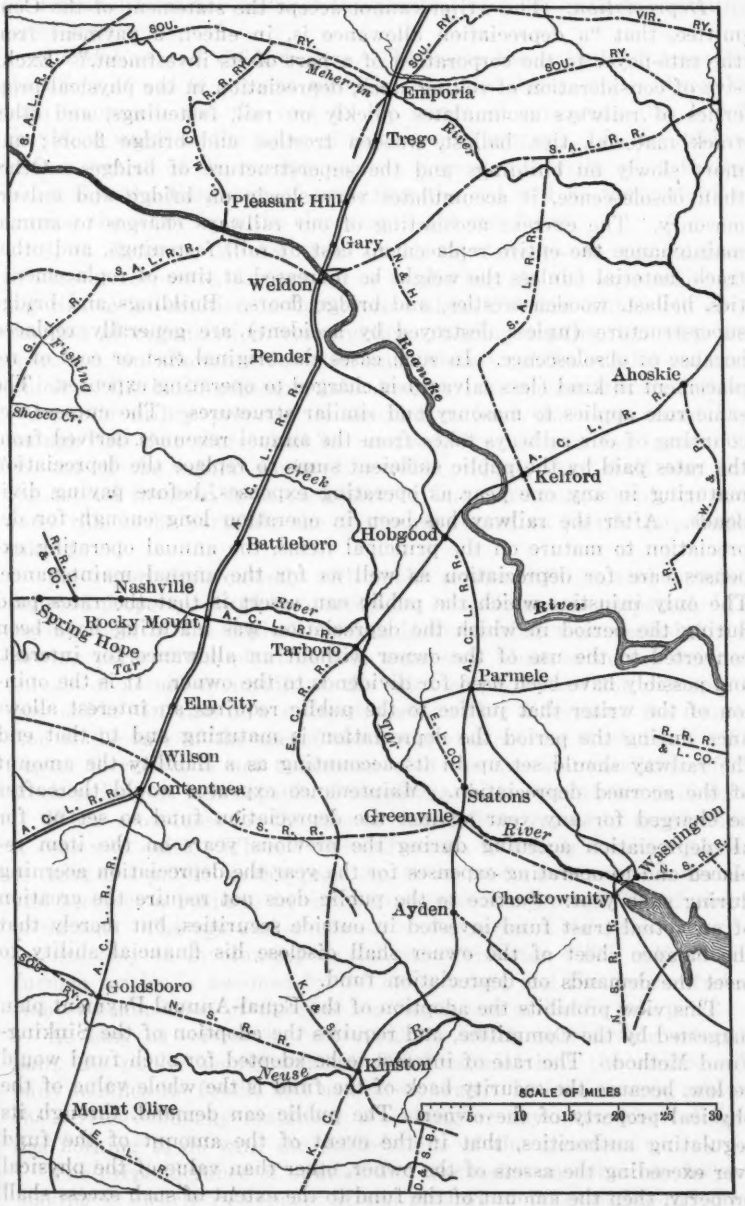

FIG. 6.

Mr. Willoughby.

Depreciation.—The writer cannot accept the statement of the Committee, that "a depreciation allowance is, in effect, a payment from the rate-payer to the corporation of a part of its investment." Exclusive of consideration of rolling stock, depreciation in the physical properties of railways accumulates quickly on rail, fastenings, and other track material, ties, ballast, wooden trestles, and bridge floors; and more slowly on buildings and the superstructure of bridges. Other than obsolescence, it accumulates very slowly on bridge and culvert masonry. The current accounting of our railways charges to annual maintenance the entire replacement cost of rail, fastenings, and other track material (unless the weight be increased at time of replacement) ties, ballast, wooden trestles, and bridge floors. Buildings and bridge superstructure (unless destroyed by accident) are generally replaced because of obsolescence. In such cases the original cost or cost of replacement in kind (less salvage) is charged to operating expenses. The same rule applies to masonry and similar structures. The current accounting of our railways takes from the annual revenues derived from the rates paid by the public sufficient sums to replace the depreciation maturing in any one year as operating expenses, before paying dividends. After the railway has been in operation long enough for depreciation to mature on the principal items, the annual operating expenses care for depreciation as well as for the annual maintenance. The only injustice which the public can assert is that the rates paid during the period in which the depreciation was maturing have been converted to the use of the owner without an allowance for interest, and possibly have been used for dividends to the owner. It is the opinion of the writer that justice to the public requires an interest allowance during the period the depreciation is maturing and to that end the railway should set up in its accounting as a liability the amount of the accrued depreciation. Maintenance expenses would thereafter be charged for any year against the depreciation fund so set up for all depreciation accruing during the previous years on the item replaced and to operating expenses for the year the depreciation accruing during such year. Justice to the public does not require the creation of an actual trust fund invested in outside securities, but merely that the balance sheet of the owner shall disclose his financial ability to meet the demands on depreciation fund.

This view prohibits the adoption of the Equal-Annual-Payment plan suggested by the Committee, and requires the adoption of the Sinking-Fund Method. The rate of interest to be adopted for such fund would be low, because the security back of the fund is the whole value of the physical property of the owner. The public can demand, through its regulating authorities, that in the event of the amount of the fund ever exceeding the assets of the owner, other than value of the physical property, then the amount of the fund to the extent of such excess shall

be deducted from the value of the physical property with the resulting lower service rates. Mr. Wil-loughby

Adaptation and Solidification.—Wherever the growth of grass has the effect of sod to prevent washing from the slopes, the roadway has been improved, and the cost to the owner of procuring this benefit should be added to the value of the physical property. If the roadway be in a section of the country where sod grows naturally, as in Central Kentucky, the total cost of procuring the sod will be the cost of repairing the wash from the slopes until the sod forms.

S. S. ROBERTS, M. AM. SOC. C. E. (by letter).—In any business, private or corporate, for private or public service, the expectancy giving rise to its creation is that there will be a return which will cover the cost of organization, construction, running repairs, renewals, and operation, an allowance for risk, and interest on the capital invested, which is the basic principle laid down by the Committee as follows: "A public utility property is entitled to have the rates made high enough" so that there shall be received, "not only a fair return for the use of the capital invested in such property, but shall also have the capital invested in it paid back." The consensus of opinion indicates this to be certainly the minimum return to justify any undertaking. Mr. Roberts.

The report deals entirely with public service utilities, and especially railroad property. Such properties are in their nature perpetual. The paying back of the capital consists in furnishing that needed for renewing parts of the plant as they wear out. Just as in any business, in sale of actual commodities, the sales supply means for purchase of new stock. In case of a railroad, there is this difference: the transaction is the sale of the use of the stock, and not the stock itself. The buyer, therefore, is not concerned with the age and condition of the stock so long as it is capable of supplying the use or service paid for.

When a business for the sale of commodities ceases to supply stock, it ceases to exist. When a railroad ceases to supply service, it ceases to exist as a public service property, as far as its owners are concerned, and becomes a business in sale of commodities through forced change of owners. The age and condition of the parts of the property are of essence only in involuntary or voluntary transfer. The obligation to furnish service is assumed by the new owners, and the errors of omission or commission of the past are taken care of in the sale price.

As long as service is furnished, for which only a fair return is paid, the public should consider it immaterial how the service company handles its funds, and makes renewals. In other words, whether the service company maintains a sinking or any other kind of fund, has nothing to do with the public's side of the question.

The preponderance of opinion and discussion on valuation for rate-making is clearly in support of the method of "Cost-of-Reproduction-

Mr. Roberts.

New" without depreciation. This places the old and new companies on a more nearly equal basis, and allows the older companies the advantage of the appreciation of their property, which should be their just due in reward for their foresight and risk in undertaking pioneer work.

The writer feels compelled to disagree with the Committee's conclusion as to appreciation. The growth and development of the community and of the railroad serving it are identical. The fact that the property of the community appreciates is due mainly to its advantage of location, which is due to the operation of the railroad to and through it. Their right to enjoy what they have is not questioned. At least, it is not in this consideration of rate-making. The advantage of the railroad is also one of location, whether determined through foresight or chance, which places it in a community capable of development and appreciation through transportation service. Advantage of the appreciation of the community property may be taken only through sale, mortgage, or increased rental. The same is true of railroad property. The appreciation is latent. Depreciation is an operating expense active and dynamic, a renewal of property actually given to the community together with the service rendered; it should be paid for as such, and should not be used to offset appreciation.

Some have argued, in support of the Committee's view, that the right of "eminent domain" is a special privilege to the railroad for which the public should take toll. It is true that very few railroads could be built without this right, but do they not pay full value for all property they acquire under it; and should they not enjoy all the advantages and rights of other property holders who have paid full value for what they possess? Is not the power of eminent domain, as a matter of fact, a question of public policy, so that the individual may not gain at the expense of the many, and is it not created for the public good?

To balance depreciation against appreciation seems to be taking toll twice from the railroad company. Unless the whole system of land values were changed, affecting alike the community and the railroad, is it just to take that from the railroad which is freely allowed to the remainder of the community as its just award?

Fair agreement seems to obtain on all points for which return should be permitted. The most mooted consideration remaining is the manner of providing adequate and, at the same time, equitable means for renewals, so that the return for this purpose may be spread over the period of usefulness of the parts so as to give a total return which shall be reasonably uniform and result in steady, not fluctuating, rates.

It is too trite to mention that he who deals in the future, deals with uncertainty; yet the fact remains that our best decision in regard to provision for renewal funds is an estimate. The one who must bear

the result certainly should be given the advantage of all reasonable doubts. Mr. Roberts.

Alexander C. Humphreys, M. Am. Soc. C. E., in his paper, "Depreciation: Estimated and Actual," shows the error of considering the average life of a plant as a whole in making provision for depreciation, or, as the writer prefers to express it, renewals. Mr. Humphreys emphasizes the necessity of considering separately each group of parts having the same period of usefulness. He and others give warning that, in order to hope for results sufficiently near to the probable actual performance of any part to warrant consideration, careful account must be taken of the past history of the part and of its present condition, as determined by actual examination.

Considering that the period of usefulness of a part has been determined as accurately as human knowledge and foresight will permit, now comes the problem of providing a means to secure its perpetuation.

The methods of computation form the academic considerations of the problem; the equity lies in the adoption of that method which gives just results under all conditions.

There is agreement between all writers that the Sinking-Fund Method of computation, considering return on the "Cost-of-Reproduction-New" without depreciation, is correct in ultimate result under all assumptions of rate of interest for return on invested capital and for computation of the annual increment for depreciation or renewal. It makes no difference whether the rate of interest for return on invested capital is the same or different from that used in computing the annual sinking fund or renewal increment.

It is generally conceded, too, that such a basis of computation represents a minimum permissible return, because the annual increment, must, on its receipt, be at once put out at compound interest in order to equal the necessary accumulation during the period of usefulness of the part.

Where the rate of interest allowed for return on invested capital and for computation of the annual depreciation or renewal increment is the same, the ultimate result of the Sinking-Fund Method and of the Equal-Annual-Payment Method is identical. This is shown in Table 16.

C. E. Grunsky, M. Am. Soc. C. E., in his paper, "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates",* in "Table 8, Method 1", and "Table 8, Method 3", and also in his Fig. 3, and in his explanation of the different methods, confirms Table 16.

It is evident that where the rate of interest is the same, there is a distinction, but not a difference, in these two methods, and any difference in distribution of the total annual return is imaginary.

20	100.00	3.02	5.00	0.00	7.64	0.38	8.02

The Equal-Annual-Payment Method, as compared with the Sinking-Fund Method, the basic rate of interest being the same, is simply the shifting of a part of the contents of one of two pockets to the other, without changing the total contents of the pockets taken together.

The foregoing comparison ceases to be true when, for any reason, the rate of return on the capital invested is different from that used in computing the depreciation or renewal increment:

(1) When the rate of return on the invested capital is greater than that allowed in computing the renewal increment, then the Equal-Annual-Payment Method ceases to be an Equal-Annual-Payment Method in any sense of the word, and will work a continually increasing injustice on the public service company after the end of the first year until the end of the period of usefulness of the part under consideration. This is shown by Table 17.

(2) When the rate of return on the invested capital is less than that allowed in computing the renewal increment, then the Equal-Annual-Payment Method again ceases to be an equal-payment method in any sense of the word, and will work a continually increasing injustice on the rate-payers after the end of the first year until the end of the period of usefulness of the part under consideration.

NOTE.—In Tables 16 and 17, the computations of the Committee are used.

A table will not be given to illustrate this. Such a premise can hardly be imagined to obtain in practice. It is sufficient to state that, considering a rate of return on capital at 5%, and computing the replacement increment at 7% for a period of usefulness of 20 years, the ultimate or total return at the end of the first and the twentieth years will be:

	Sinking-Fund Method.	Equal-Annual-Payment Method.
1st year.....	$7.44	$7.44
20th "	7.44	9.26

The Sinking-Fund Method and the Equal-Annual-Payment Method are thoroughly discussed by Mr. Grunsky in the paper, previously referred to, as "Method 1" and "Method 3", respectively, and their relative advantages and disadvantages are described by him as follows:

"Method No. 1 [Sinking-Fund Method] is always applicable when it can be shown that earnings have been adequate in the past, no matter whether the property is a single item, or is composed of many items; whether the expectancy is long or short; whether the expectancy is uniform for all parts of the property or not; whether the plant is of mature age or not; whether the property has attained full growth

Mr. Roberts.

or whether it is still growing at a uniform rate, or otherwise. It is simple of application, and does not involve determination of the present condition of the property, provided that it is maintained in proper condition to render adequate service. It furnishes all the information necessary for intelligent action in fixing rates, because when it is known what the net earnings, above operating expenses, must be to yield the return which money should earn in ordinary safe investments, then an arbitrary addition can be made, to compensate the owner for management and risk of loss.

"In contrast with these advantages, Method No. 3 [Equal-Annual-Payment Method], under which value as ordinarily understood must be determined by deducting depreciation from the investment, requires a special determination of value for each item of which the property is composed, and a new determination every year for every item, or in special cases, for every group of items of the same expectancy. Each item has a new value each year and a remaining life which grows continually shorter. Amortization, therefore, must be estimated on a new basis each year. The judgment of the expert is called into play to determine the condition and probable remaining life of the several parts of the property, and after the complex calculation is made, if the same basic rate of interest is used throughout, the result should agree absolutely with the simpler Method No. 1."

No greater part of the investment is returned to the investor by the Equal-Annual-Payment Method than by the Sinking-Fund Method. The Equal-Annual-Payment Method is more difficult to compute, and gives correct results only under the condition of equal basic rates of interest.

If Table 16 is correct, then in Table 6,* of the Committee's report it is evident that part of the return on the capital invested is shown reinvested in additional plant as "earnings for depreciation". Also, at the end of the first year, after the depreciation or replacement increment of $7 238 is reinvested in additional plant, the plant is furnishing all the service any $107 238 plant could possibly furnish. The original $100 000 investment and the $7 238 investment, as far as the plant and service are concerned, and as far as ultimate return is concerned, should be treated as entirely separate and distinct investments, each of which enjoys in every respect the same and all rights and privileges accorded to capital to earn.

The illustrations of notes and their payment used by the Committee do not appear to be in all cases *apropos,* for the reason that the perpetual or continuous nature of the property is not considered. That is, that something in railroad properties, termed "Latent Depreciation", by Richard J. McCarty, M. Am. Soc. C. E., in his paper, "Depreciation of Railroad Property", is not taken into account.

The adoption of the term "depreciation fund" seems, in a way, extremely unfortunate, and to it may be attributed much of the mis-

* "Addition to the Progress Report of the Special Committee."

understanding of the purpose for which it is created; especially in the minds of those not thoroughly familiar with the whole subject. Although, of course, this notation arises from the fact that the basis of computation of the fund is wear and tear, and final exhaustion, still the fund is not for depreciation, but for continuation and perpetuation, and is, it seems, more happily expressed as a "Renewal Fund", which certainly is its purpose. The rate-payers get the whole of the plant, along with their service. The "Renewal Increment" is proportional to the rate at which the plant is used up by them. The "Renewal Fund" is something due the service company, not something to be taken from it. Mr. Roberts.

The writer believes the "Sinking-Fund" or "Renewal-Fund" Method to be generally more equitable than the proposed "Equal-Annual-Payment" Method.

Considering that it requires all the "Renewal Increments" increased by all their interest accumulation to equal the "Renewal Fund"; considering the uncertainty of forecasting future performance; considering the advance of the art which frequently requires the renewal of parts before their expected period of usefulness can be enjoyed; considering the mature age of the majority of railroad properties, which have reached that stage where renewals are uniform and constant; that is, considering the "risk", liberality should be used in dealing with the allowance for and make up of the "Renewal Fund".

C. P. HOWARD,* M. AM. SOC. C. E. (by letter).—The "Sinking-Fund" Method provides: Mr. Howard.

(1).—Equal annual payments, which at compound interest will amount to the full value of the plant at the end of its life.

(2).—Return on capital computed for the full value of property.

The owner then receives a return (say, 7%), on the full value of his investment throughout its life; and the sinking-fund increments put out at compound interest (say, 5%), will return him the full value of the plant at the end of its life. If these increments, computed on the basis of 5% interest, were by good management invested at 7%, the owner would have a surplus of more than enough to renew his plant.

The "Equal-Annual-Payment" Method provides for the repayment of the invested capital. Mr. Roberts points out that this gives a considerably less return to the investor than the Sinking-Fund Method, when depreciation allowances are calculated at a less rate of interest than return on capital.

The reason for this is obvious. If the owner could re-invest immediately each depreciation allowance in the plant, or in other business, which would earn 7%, without any loss of time, or development period, he would at all times have 100% capital invested with annual returns

* Previous discussion by Mr. Howard appeared in *Proceedings* for February, 1914, on p. 387.

Mr. Howard. of 7%, as indicated in Table 6, of the Progress Report. Of course, he could do better than this with the larger payments received under the Sinking-Fund Method; but the very reason for computing sinking-fund increments at a lower rate of interest is the supposition that capital must be kept on hand and available for more or less irregular expenditures, as they occur. It must be ready cash. If it is re-invested, the company will have to go to the expense of borrowing on short-term notes or some other method of securing ready cash.

Referring again to Table 6, and what it implies: Is it reasonable to suppose that the company can always immediately re-invest every dollar in improvements and extensions? Except to a limited extent, it is evident that improvements and extensions cannot be planned and financed in such manner; and, if they could, it would be idle to expect full earnings from the start. It is possible, of course, that a part of the fund might be re-invested from time to time at 7%, the rest remaining on deposit at a lower rate of interest, say 3 per cent. The average interest return on the sinking fund would then be somewhere between—say, 5 per cent.

The matter could be handled easily enough under the Sinking-Fund Method, whatever disposition is made of the fund. The only thing to decide is what is the reasonable average rate of interest at which the sinking fund may be expected to accumulate when invested under ordinary conditions with reasonably good judgment.

Mr. Mortimer. JAMES D. MORTIMER, ESQ. (by letter).—Judging by the title, the Committee has confined its preliminary report to valuation for the purpose of rate-making. There are other purposes for which a valuation may be made, such as purchase and sale, taxation, municipal or governmental acquisition, etc., which would introduce other elements of value.

As the report is preliminary and the discussion now called for partakes of a like nature, the writer's remarks are purposely brief, and designed to sketch the line of investigation of statistical and economic principles now being conducted by several public utilities and the Bureau of Fare Research of the American Electric Railway Association.

1.—The process of assembling the elements of value is very much simplified by concentrating the attention on the property of the utility, as distinguished from that of the corporation owning it. The utility is the entity possessing the franchise or permit to occupy the streets, the physical property used or useful in the performance of the public service, and the other assets necessary to the operation of the complete plant. This conception is much simpler than that of principal and agent, which some have recently endeavored to introduce for the purpose of defining the relation between the State, the public, and the public utility corporation.

Mr. Mortimer.

2.—The determination of the valuation for the purpose of rate-making consists of assembling the elements of value or assets of the utility. These assets consist not only of the physical property used or useful, but also all other assets, such as accounts receivable, which the utility may have owing to it by the corporation. Many of the reserve liabilities of the corporation, such as depreciation reserve, fire insurance reserve, injuries and damages reserve, are, in the proper accounting conception, assets of the utility and entitled to consideration in determining its value.

3.—In dealing with the subject of depreciation it is of importance that the various conceptions be recognized and distinguished, *viz.:*

(*a*) Rate at which depreciation is accruing at the moment or during the current year;

(*b*) Rate at which depreciation has accrued during the previous life of the unit of plant;

(*c*) Rate at which depreciation will accrue during the remaining life of the unit of plant;

(*d*) Annual reserve required to finance replacements as they occur from time to time;

(*e*) Accumulated depreciation measured by loss in value or utility;

(*f*) Accumulated depreciation reserve necessary to finance replacements as they occur from time to time.

No satisfactory definition of accrued depreciation or depreciated value has yet been developed which does not bear some relation to the estimated amount of money which would have accumulated under some plan of annual payments commencing at the time the unit of plant was placed in operation. Whether the problem of measuring accrued depreciation scientifically, by either inspection or statistics, will be separated from that of financing replacements, cannot now be predicted with any certainty.

4.—The actual future life of any particular unit of plant ascertained by inspection is indeterminate. Only the boundary conditions are questions of fact; the unit may be either new or about to be abandoned. With respect to all intermediate conditions, the facts are indeterminate; abandonment may occur to-morrow or 10 years hence.

5.—Experience and general observation show that there are usually two concurrent forces acting to limit life, that is, to require replacement or abandonment. These two forces are probably present in different relative proportions in each class of equipment, and it may be that in many classes either one or the other may be almost entirely absent. These two forces are defined as follows:

(*A*) The force causing destruction, remaining constant throughout the life of the unit, acting equally on new and old, and covering destruction arising from chance, such as accident,

Mr. Mortimer.

governmental requirement, inadequacy, improper design, and engineering errors in design, selection, and construction.

(*B*) The force causing destruction, increasing directly with age, acting on the old in greater proportion than on the new, and covering destruction arising from wearing out or other causes which vary directly with age, such as obsolescence and natural decay.

The relative proportion in which these two forces are present in any class of equipment cannot be determined until after the causes of depreciation have been quantitively measured in the light of a proper gathering and assembling of actual data.

If L = proportion of original number living at age, t; then,

$L = e^{-At}$, where only the force, A, is present;

$L = e^{\frac{-Bt^2}{2}}$, where only the force, B, is present; and,

$L = e^{-t\left(A+\frac{Bt}{2}\right)}$, where both forces, A and B, are present.

Where e is the base of the natural system of logarithms.

6.—The problems involved in the determination of the proper amount to be included in operating expenses, to insure the replacement of the various plant units, are similar to those involved in the calculation of life insurance premiums. The amount, per dollar invested in a particular plant unit, required for such property replacement insurance depends on the age of the unit, the mortality table of a group of such units, the reserve already accumulated, the rate of interest allowed on accumulations in the reserve, and the evident state of preservation of the unit. The accumulations in reserve may be drawn on at any time, depending on the contingencies requiring the abandonment of the unit of plant. As the maturity dates of the loans making up the depreciation reserve of the utility are indeterminate, and may be one day or several years, the loan is entitled to a rate of interest comparable with that allowed on daily bank balances or the rate of interest assumed in calculating life insurance premiums, say, 3 per cent. This interest rate should be distinguished from that assumed for depreciation calculations, where an average life is estimated and the deficiencies in interest and reserve accumulations arising from early mortality are assumed to be offset by the greater interest accumulations during years beyond the assumed mean life. If the replacements required in a typical complete plant be set down in detail during a period of time running beyond the average life of the plant, it is found that the allowable interest rate resulting from interest accumulations is very low, approximating 2% in the case of some plants having an estimated average life in excess of 30 years.

Mr. Mortimer.

7.—The rate of interest allowed on depreciation reserve accumulations is a very different quantity from the rate of return to be allowed on permanent investment in plant; the former may be withdrawn in large part at any time, but the investment in operating plant must remain until worn out or otherwise abandoned. It is also important at this place in the discussion to recognize the fact that public utilities as viewed in law are presumed to operate in perpetuity, and the owners of a utility cannot withdraw the capital invested in any plant unit when the depreciation reserve has returned an amount equivalent to the original investment. These owners, by virtue of the public functions assumed on behalf of the utility, are required to continue the plant in operation and make the needed replacement. In view of the obligations assumed by the utility, it is unreasonable to assume that accumulations in the depreciation reserve, created, as they may be, from payments by the users of the service, are in the nature of repayment to the owners of the utility of their capital investment. Only in the case where such depreciation reserve accumulations were distributed in the form of interest and dividends on securities of the corporation can it be said that there has been a withdrawal of the invested capital.

8.—From the nature of the property making up a public utility, the problems of valuation and rate-making should be the same, whether the utility be owned by a municipality, the State, an individual, a partnership, association, or corporation. Regulation has primarily to do with the functions of the utility. In the broad sense, the law has no interest in the nature of ownership of the utility, except to the extent that it prescribes and limits the powers of the particular entity in which such ownership may be vested. If these statements be true, it follows that capitalization, dividend record, and ratio between outstanding bonds and outstanding share capital, have no direct relation to the regulation of rates of a public utility owned by a corporation. Likewise, the rate-payers have no interest in stock dividends or book surplus appearing on the books of the corporation.

9.—These considerations permit one to draw the distinction existing between the "going cost" of the utility and the "going value" of the corporation, shown in the latter case by the excess of market value of securities over the cash cost of property acquired thereby.

10.—Specific comments might be made on various parts of the Committee's report, but it is doubtful whether space and time available for the present discussion will permit. Summarized, the principal defects in the Progress Report of the Committee are as follows:

(*a*) An erroneous conception of the function of depreciation allowances is adopted. Depreciation allowances are not repayment of capital unless actually disbursed as interest

Mr. Mortimer.

and dividends, and then only when and to the extent that the utility has earned a reasonable return.

(*b*) Depreciation reserve credits appearing on the books of the corporation are among the working assets of the utility, and hence additive to the reproduction cost for the purpose of determining valuation for rate-making; and, if any utility and its corporation have reserved 100% of the estimated accrued depreciation reserve, there results a sum equal to the reproduction cost new.

(*c*) Permanent investments in operating plant, of depreciation reserve accumulations, are entitled to the same rate of return as are investments of the proceeds of bonds and share capital.

(*d*) The very large probable errors contained in all present-day estimates of depreciation allowances, arising from lack of data covering the useful lives in service of various units of plant, do not justify extended discussion as to the relative merits and equity of the "straight-line", "sinking-fund", and "equal-annual-payment" methods. When the principles of actuarial science are properly applied to the problems of depreciation, much minute discussion of unimportant arithmetical methods will be avoided and some definite progress will be achieved.

(*e*) Substantial revision in the economic theories and mathematical principles of the Committee is required before its report can receive general adoption by engineers, public utility operators, regulating commissions, and the Courts.

Mr. Churchill.

CHARLES S. CHURCHILL, M. AM. SOC. C. E. (by letter).—After carefully studying the report of the Special Committee, and after reading several published discussions thereon and listening to an explanation by the Chairman, Mr. Stearns, followed by several verbal discussions, the writer is greatly disturbed by the differences in interpretation of its meaning and the consequent dangers that may result in case it is accepted as the views of the Society on this particular subject.

The writer is particularly impressed with the thought that the questions raised therein are as much legal as engineering in character, or more so, and while not criticizing the Committee for taking a different view, he nevertheless felt himself not altogether competent to pass judgment on these legal questions. He, therefore, submitted the report to a legal friend for his opinion. In much of what follows the writer is indebted for suggestions to this friend, who, though he has no desire to take part in the discussion, has no objection to this use of his opinions.

Mr. Churchill.

In its opening statement the report advises that the Committee preparing it was appointed in September, 1911 (which was prior to the enactment of the Federal Valuation Law), and that it was "to formulate principles and methods for the valuation of railroad property and other public utilities", but that it has submitted "a report covering the subject of Valuation for the Purpose of Rate-Making". Thus, what the Committee was to do, according to its own statement, and what it has done, as appears from its report, do not agree.

Subsequent to the appointment of the Committee, Congress enacted a Valuation Law applicable to "all property owned or used by every common carrier" subject to the provisions of the "Act to Regulate Commerce", which law became effective by the approval of the President on March 1st, 1913. The report of the Committee is made as of December 1st, 1913, for submission to the Society at its Annual Meeting on January 21st, 1914, and yet this Federal Law, which is absolutely controlling in the valuation of railroad properties, and had been in force for 9 months prior to the date of the report, is not referred to in that report, nor was the report prepared with any reference thereto, as is shown by its contents.

The purpose of the Federal Valuation Law is to obtain the value of the various railroad properties of the United States. This law in its opening statement provides that the Commission "shall, as hereinafter provided, investigate, ascertain, and report the value of all the property owned or used by every common carrier subject to the provisions of this Act". Further, it provides that "such investigation", by the Commission, "shall show the value of the property of every common carrier as a whole, and separately the value of its property in each of the several States and Territories and the District of Columbia, classified and in detail as herein required"; it provides that "All final valuations by the Commission and the classification thereof shall be published and shall be *prima facie* evidence of the value of the property in all proceedings under the Act to Regulate Commerce, as of the date of the fixing thereof and in all judicial proceedings, etc."; it provides that the Commission, in addition to investigating, ascertaining, and reporting "original cost to date", "cost of reproduction new", and "cost of reproduction less depreciation", shall, in like manner, "ascertain and report separately other values and elements of value, if any, of the property of such common carriers".

Judge Prouty, Director of Valuation under this law, in a speech on February 11th, 1914, before the United States Chamber of Commerce, said "Up to the present time the holding of the Supreme Court of the United States is, that the cost of reproduction new, or cost of reproduction less depreciation, are only factors entering into the final question of value. Many other things have been enumerated by that Court as bearing upon the value of the property". Again, in the same

Mr. Churchill.

speech, he said "I simply call your attention to the fact that the Commission is required, not merely to ascertain the cost of reproduction, but to state the value of the property, and that in attempting to do so many delicate and difficult questions may be encountered".

The law, thus ascertained, clearly directs that "the value" of the property shall be ascertained. The purpose of this value, whether for the regulation of the issuance of securities, for the protection of investors, as suggested by Judge Prouty, for making rates or for testing or limiting them for taxation, or for some other purposes, is not stated. The valuation may serve many purposes, but whatever the purpose, it is "the value" of the property that must be considered. The law requires "the value" to be reported. Thus it reads and thus has Judge Prouty publicly construed it. No reason, therefore, exists and no purpose is now to be served, when the great work of ascertaining "the value" of "all the property" of every common carrier subject to the law is going on, for discussion, consideration, or conclusions on a particular kind of value, namely, a value for rate-making purposes, because such special values as this are not now under consideration by the Government and are not involved under the Valuation Law.

In the Summary (page 70 of the report), Paragraph 1 reads:

"This report is limited to the discussion of valuation for the purpose of rate-making. Valuations for other purposes differ in some respects, for legal and other reasons".

Also, on page 1 of the report, the Committee says:

"Valuations of the property of public service corporations may be made for a variety of purposes, the most important of which are the furnishing of a basis for the regulation of rates, and for taxation, capitalization and purchase".

It is manifest from this language and from a reading of the entire report that the Committee has been more concerned with a certain "purpose" of valuation, namely, rate-making, than with valuation itself. The Committee proposes methods for arriving, not at "the value" of the property, but at a sum or an amount of money, which, while it will not be the value of the property, will be the value on which the Committee recommends the carrier should be permitted to earn.

The Committee is not happy in the language it uses, as a justification for its course, namely:

"It is sometimes held that valuations for all these purposes [regulation of rates, taxation, capitalization and purchase] should give identical results. This view cannot prevail if the laws of the different States and certain decisions of the Courts are complied with. For instance, there are many State laws indicating how the property of public service corporations shall be valued for taxation and these laws differ radically in their requirements. There are other reasons why the valuation for different purposes should differ, but this feature will not be

discussed at present as this report will, as stated, relate to valuation for the purpose of rate-making". Mr. Churchill.

The omission of these "other reasons" and of any reason whatever for the statement that value for capitalization, for purchase, and for rate-making, is not the same, detracts greatly from the report. The mere fact that one State may tax public service corporations on income, another State by license, and another by *ad valorem*; or that one State using the *ad valorem* method may assess the property at one percentage of its value and another State, using the same method of taxation, may tax at a different percentage of value, illustrates nothing as to value. One State prefers one method of taxation and another State a different method. The fact that different States use different methods of taxation is not even suggestive that the measure of "the value" of the property varies in the different States.

To assume, as the Committee evidently has done, that the American Society of Civil Engineers has instructed it to report on the valuation of railroads "for rate-making purposes", or to assume that the Society will sanction the report though unauthorized, is, in each case, scarcely authorized. In the first case the directions to the Committee are in opposition to the assumption, and, in the second case, the long-established reputation of the Society for the broad treatment of all subjects coming before it equally opposes the presumption there indulged. When has any State ever made a tariff of rates or an individual rate for any railroad based on the value of the railroad's property? What State has ever proposed to do so? How would it be possible for a State or for the Federal Government to do so? A railroad may invoke the value of its property, as has been done, to show that an entire body of rates is confiscatory. In such case, however, it is not some peculiar kind of special value that is invoked, but "the value" of the property. The Constitution does not recognize fantastic differences over supposed different kinds of values, but it protects "the value" of all property, whether that of a common carrier or of some one else. It may be desirable for the Government—State or Federal—to be possessed of official information as to "the value" of a given carrier's property, so that, if a charge of confiscation through rates which are too low is made, the Government will be armed with the facts and will not be dependent on the evidence of value furnished by the carrier, and such, perhaps, is the purpose, or one of the purposes, of the Valuation Law. Manifestly, if such be the purpose, the only value that will be worth anything to the Government—State or Federal—if the charge of confiscation under the Constitution be brought against it, is "the value" of the property. Any figure admitted to be less than the true value of all the property of the carrier, will be worthless, as long as the Constitution stands, and, therefore, labor and cost now expended to obtain such a figure are time and money thrown away.

Mr. Churchill.

There may be a relation between the total net earnings of a common carrier and the total value of all the property of that carrier, speaking always of value as actual value, but there is not, nor can there be, any relation between the total value of all the property of a carrier and one of the individual rates of that carrier. The carrier may be earning a total that furnishes unusually large dividends and yet the particular rate involved may be unduly or unreasonably low, or necessarily fixed by competitive or other conditions.

On the other hand, a carrier may not be earning any dividends, it may not be paying all its fixed charges, and yet the particular rate at issue may be unreasonably high. The reasonableness of the individual rate must be determined in each instance on other considerations than the value of the carrier's property. Under the law each individual rate must be "reasonable", and whether the roadbed of a carrier cost $10 000 or $200 000 per mile to construct, and whether the carrier claims or proves its property to be worth one sum or another, it can never exact under the law any more than a reasonable charge for each particular service that it performs. Thus is the public protected against supposed or actually inflated values, if made or claimed by the carrier. On the other hand, the carrier is entitled, under the law, to make a reasonable charge for each particular service that it renders, so that, regardless of any theoretical, imagined, or depressed value that may be put on its property, it may continue to demand a reasonable charge for each of its services, and thus it is protected. It is true that the term "reasonable" is an elastic one, and throughout all the years in which various commissions have been applying it, no uniform rule for its application has ever been established. This does not mean, however, that it has not been applied, nor that eventually more general rules for its application will not be evolved. Heretofore, each individual rate case has been determined on its own peculiar facts, and such will be the situation after the carriers have all been valued and until such time as uniform rules may be worked out. When worked out, and in the process of working them out, it will be found that, save in the case of a body of rates attacked as confiscatory, the value of the carrier's property will probably cut no figure; but whether or not this be true, it will certainly be found true, as long as the present Constitution exists, that in the making or unmaking of railroad rates—either as a whole or individually—by Government decree, the only value of the property of the carrier that can be considered is its actual value, or, in other words, "the value" authorized and directed by the law to be obtained.

Judge Prouty, in his speech before the United States Chamber of Commerce, to which reference has already been made, used this language:

"The rates of public utilities are at the present day usually fixed by Commissions, both State and Federal. It is perhaps the natural

Mr. Churchill.

inference that when the value of the property has been determined and the rate or return fixed, the work of the Commission in establishing the charge of the public utility is comparatively easy. It is only necessary to multiply the value by the rate and to allow a charge which will yield that income. And this, with some important qualifications, is true as to certain kinds of public utilities. Take, for instance, a water plant or a gas plant. This serves a single community. As a rule it meets no competition in that service. The amount of service is known or can be forecast with reasonable accuracy. Even matters of depreciation and such like have come to be pretty actually understood. It is possible, therefore, to fix with some confidence the rates of such a utility, when the value of the investment is known. With the railroad, however, this is entirely different for the reason that it seldom happens that a single railroad can be considered by itself. The greater part of the business of the railways of the United States is subject to competitive conditions of one sort and another, which are largely controlling so that the rates of one are necessarily bound up with those of another".

Also:

"The railroads of this country are so bound up together that their rates are largely interdependent. It is impossible to shake a single railroad free from every other and fix its charges upon the basis of a fair return upon its fair value as you would in case of a gas or water plant."

Also:

"While, however, I wish to make it perfectly plain that the problem of establishing railroad rates will not be solved by this valuation, I desire to say with even greater emphasis that the problem will be enormously simplified. It can be known with certainty whether the general level of rates is or is not too high and in establishing the charges to be observed by a single carrier, even in fixing the rate upon a single commodity, it will be of much benefit to know the value of the property involved".

All of which means that, in the opinion of Judge Prouty, and as any serious consideration of the subject will show, there is not in law or reason any such thing as a special value different from real value on which to base railroad rate-making, and that the only value of use or service in any degree in the testing or making of rates is "the value" of the property. Judge Prouty, in making rates for a gas or water plant, would want to know "the value of the investment" and not some fanciful and untrue value based on a theory. In the case of railroads, as we have heretofore seen, he construes the law to require "the value" of the property to be ascertained, and now we see that when "the value" has been ascertained, he cannot solve the problem of rate-making on that value. The most he can say is that, knowing "the value", he can know with certainty whether the general level of rates is too high or too low, and that in other respects it will be of much benefit to know "the value" of the property. What this benefit will

Mr. Churchill.

be he does not say, but, accepting his statement that there will be a benefit, it is important to note that the benefit will come from knowing "the value" of the property. The problem of railroad rate-making is an involved and complicated one. Many and conflicting elements enter into it. With such a problem to solve, it should require no argument to demonstrate that injecting into it a fanciful and untrue value of the property involved, not only adds nothing to the solution of the problem, but actually destroys any test of whether the general level of rates is too high or too low.

On page 9, the Committee states that in examining accounts to secure costs of a property that is not old, "it will be necessary to scrutinize the accounts and to examine the property to ascertain whether the construction was carried out in a judicious manner. * * * whether the cost was reasonable".

The writer submits the opinion that, without living witnesses, it is doubtful whether disapproval of properly kept accounts would or should stand when made by any outside party not personally acquainted with the property and its history.

Page 10 of the report is evidently written with the erroneous idea that maintenance, replacements, depreciation, and obsolescence of a railroad, say, 50 years old, has not been generally covered by charges to operating expenses or from income; and, further, under the assumption that on ordinary railroad properties care has not been usually taken to charge to capital account not more than the true betterment or addition. The Committee is in error in making such a sweeping assumption the basis of one of its important conclusions adverse to the records of railroads.

The law directs the Commission to report "original cost to date" of all the property of each carrier, and the duty of the Commission to ascertain and report the figures representing such cost is mandatory; notwithstanding this fact, however, the Committee, instead of offering helpful suggestions for the discharge of the duty, ignores the requirements of the law and on page 11 of its report says: "For reasons given, the Committee believes a valuation of an old property based on its actual cost to be generally impracticable, making it necessary to adopt the cost-of-reproduction method".

On page 15 of the report, the Committee says:

"In view of these and other considerations, the Committee is of the opinion that valuation should be based upon the physical conditions existing at the time the various portions of the property were built, but at the prices prevailing at or near the time of the valuation".

It is to be observed (*a*) that the Committee, ignoring the law under which railroads must be valued, gives no consideration to "original cost to date", which the Commission must ascertain and which will show what it actually cost to construct the property under the condi-

Mr. Churchill.

tions existing at the time of construction; and it is also to be observed (*b*) that the Committee is clearly influenced in its suggestion by the "purpose" for which it would get a certain kind of value; for certainly it would seem that if the physical value of a certain property is the cost of reproducing that property, then the cost of reproduction to be ascertained is the cost to-day, for it is the value of the property to-day —at the time it is being used—and not a value existing years ago, to which the protection of the Constitution extends. For all purposes of value it is the value "to-day" which is involved, and which must be shown.

On page 18 the report reads:

"Although the Committee believes that in such cases as those cited the property to be valued is that which the corporation has paid for rather than that to which it holds title, there are obviously many cases in which property donated to the corporation should be included in the valuation."

On page 50, it reads:

"Your Committee is aware that the decisions of the higher Courts indicate that present prices should be used in making a valuation of land as well as of structural property, and that the present practice generally gives to the corporation as to the individual the so-called unearned increment due to appreciation in land values.

"This is incompatible with the fundamental principle that the corporation is entitled to a fair return upon the fair value of its property, because, if the land is valued at the increased price, and the appreciation in the value of the land is included in the accounting, the corporation would receive a sum in addition to a fair return, amounting to the appreciation in the value of the land."

On page 74, it reads:

"*Adaptation and Solidification* should be included in the valuation to the extent that they may have involved the expenditure of money. The increased value due to adaptation and solidification which has resulted from the action of the elements and natural causes without the expenditure of money should not be so included."

These quotations, and others which might be made, show the intention of the Committee deliberately to exclude from its valuation of a carrier's property certain distinct items and elements of value, so that, as we have heretofore seen, the result of a valuation reached under its recommendations would confessedly not be "the value" of the property. Not being and not pretending to be "the value" of the property, of what service would its valuation be? So far as a given railroad property is concerned, it has already been shown that given the true actual value of all its property, tariff rates for it could not be predicated thereon. This being true, what could any one possibly do with figures not representing "the value" of the property?

Mr. Churchill.

The error of the Committee in making its report is fundamental. On page 6, it is said:

"It has been well settled by the highest Courts that the owner of such property [public service property] is entitled to a fair return upon a fair value of the property utilized in or reasonably necessary to the service."

Without at this time entering any dissent to this statement, attention only is called to the fact that throughout the report, the Committee has made the fundamental error of misconstruing and misunderstanding the basic principle of its report as thus stated. In other words, the Committee, as clearly appears, has proceeded on the assumption that "fair value" means something less than real value, and, so proceeding, has sought to work out a rule, by which, in valuing property, a figure may be arrived at, which, although less than "the value" of the property, will be its "fair value". The Committee, departing from substance, has wasted its energies on shadows; for "value", "fair value", and "reasonable value" mean the same thing, under the Constitution. If, however, by a play on shades of meaning, it is held that "fair value" is something less than "value", then only the figures representing "the value" are of any use when the Constitution is invoked. "Fair value" means no more and no less than "the value" fairly ascertained. The use of the word, "fair", may imply a limitation to the extent that "the value" required shall not be "fictitious value" nor "excessive value"; but it is likewise a limitation to the extent that "the value" required shall not be less than "actual value". The value required is not that which is fictitiously or excessively high or low, but is the real value fairly and reasonably ascertained.

In the Minnesota Rate Cases (230 U. S.), referred to by the Committee, the Court, quoting from Smyth *vs.* Ames (169 U. S., 546), said:

"The basis of calculation is the 'fair value of the property' used for the convenience of the public", but proceeded immediately to add: "Or, as it was put in San Diego Land & Town Co. *v.* National City [(174 U. S., 739)]:

"'What the company is entitled to demand in order that it may have just compensation is a fair return upon the reasonable value of the property at the time it is being used for the public.'"

Thus, the Court clearly implied that "fair value" and "reasonable value" were, for its purposes, synonymous terms. A few lines farther on in the opinion of Mr. Justice Hughes, from which these quotations are taken, he proceeds to quote with approval a further statement from Smyth *vs.* Ames, to wit:—"What the company is entitled to ask is a fair return upon the value of that which it employs for the public convenience". Thus, "fair value", "reasonable value", and "value" are used by the Court as interchangeable and synonymous terms. Later, in the opinion of Mr. Justice Hughes in the Minnesota Rate Cases, he

uses the following language: "It must be remembered that we are concerned with a charge of confiscation of property by the denial of a fair return for its use; and to determine the truth of the charge there is sought to be ascertained the present value of the property." Thus emphasizing again that it is actual value that must be ascertained. Mr. Churchill.

The law requiring the ascertainment of "original cost to date", which requirement the Committee ignores, proceeds to say:

"Fourth. In ascertaining the original cost to date of the property of such common carrier, the Commission, in addition to such other elements as it may deem necessary, shall investigate and report upon the history and organization of the present and of any previous corporation operating such property; upon any increases or decreases of stocks, bonds or other securities, in any reorganization; upon moneys received by any such corporation by reason of any issues of stock, bonds, or other securities; upon the syndicating, banking and other financial arrangements under which such issues were made and the expense thereof; and upon the net and gross earnings of such corporations; and shall also ascertain and report in such detail as may be determined by the Commission upon the expenditure of all moneys and the purposes for which the same were expended."

The Committee, in its report, page 65, says:

"It is the view of the Committee that an excess of deficiency of past earnings of an unregulated property should not be considered in making a valuation of the property, except as they may be useful in determining the development expenses. The Committee has been led to reach this conclusion, not because it would necessarily be inequitable to consider such past earnings, and especially recent earnings, but there seems to be no rational basis upon which they can be included. They are important as indicating whether rates are too high or too low.

"If one attempts to consider past earnings in making a valuation, many questions arise, Shall the consideration include the earnings for 2, 5, or 10 years, and if so, why not for a much longer period?" * * *

One has but to contrast this view of the Committee with the law to which it applies, to see how hopelessly apart the Committee and the law are. The law requires all "earnings" and all "expenditures" to be ascertained. The Committee say these things should not be considered. The law would have them considered in ascertaining "original cost to date", but the Committee, as we have seen, would not obtain that cost. The "excess or deficiency of past earnings of an unregulated property" will be considered by the Commission, because the figures will be ascertained and will be of a period, in many cases, when there were no regulating commissions. Of what value, therefore, is the recommendation of the Committee that the Commission must not do that which the law says the Commission must do?

On the subject of depreciation, the report deals at length and most interestingly. There is much said in this connection which is of value and will be helpful hereafter in solving this problem. There runs

Mr. Churchill.

throughout all that is said, however, the same fundamental error which pervades the entire report, and that error is the purpose to obtain a figure for "value for rate-making", in lieu of one that will be "the value" of the property. So understood, the Committee's recommendations for ascertaining depreciation cannot be considered. The law requires that, as to a given existing piece of physical property, there be ascertained the cost to reproduce it new, and that there be then ascertained the extent or amount to which that existing item has deteriorated from new, which will be the depreciation, and which amount, being deducted from that representing the cost new, will give the present value of the existing item as it stands. This is a simpler statement of what depreciation is than the process for determining its amount may be, but it is a statement wholly unsatisfactory to the Committee.

On page 33, the Committee sets up what it calls an Equal-Annual-Payment Method, which, it acknowledges, it is not feasible to comply with exactly; and, on page 34, it is shown that it is equal only because the Committee has shrewdly chosen for illustration property of 20 years' life, and an interest rate of 5 per cent. It is shown on the same page that it is not equal in any other combination. It is acknowledged, on page 36, that "it is impracticable to devise any rule which will provide for strictly equal annual payments if the cost of repairs and operation is included".

Yet this is just what railroads have successfully done for years with fairly average annual expenditures covering repairs, replacements, renewals, and including the various forms of depreciation. Hence, why should the Committee endeavor to set up a scheme primarily calculated for local water-works, pipe lines, etc., and try to make it apply to railroads which have been purposely designed so as to allow of economical replacements of their elements in such a manner that the railroad property as a whole may always be kept practically at about 100% efficiency and value? It seems that the Committee in seeking methods of bookkeeping has laid aside the practical and correct methods which have been in use for years, and which it has failed even to attempt first to disprove.

The report, page 32, says:

"A depreciation allowance is, in effect, a payment from the ratepayer to the corporation of a part of its investment, and such part of the investment as has thus been repaid should not appear in subsequent valuations of the property."

On page 37:

"Assuming the Committee's views to be correct, that a depreciation allowance is a return to the corporation of a part of its investment in existing items of property, the money so returned should be treated as a part of the capital and used for any purpose for which the corpora-

Mr. Churchill.

tion is authorized to use capital, namely: for additions, replacements, betterments, or the extinguishment of outstanding obligations."

On page 38:

"Depreciation allowances should be such that the corporation shall have received, when its property is worn out or become obsolete, neither 50 nor 150% of its value, but as nearly 100% as the best methods of determining the depreciation allowances will permit."

On page 49:

"It will be observed that the writers in all these cases ignore the fact that a depreciation allowance earned from the rate-payers is a return of a part of the investment, and that after that part of the investment is returned, it is neither inequitable nor confiscatory to base future returns upon the depreciated value, which is the remaining investment in the property."

It seems quite clear from these quotations, and from others that might be made, that the purpose of the Committee in dealing with depreciation is to obtain what in its judgment will be a fair "depreciation allowance", and not the actual existing depreciation as affecting present value; and that the end to be reached is not the value of the property in its depreciated condition, but the "remaining investment" in the property, after the original investment has been depleted by whatever depreciation allowance has been "earned from the rate-payers". Interesting as all this may be, can any one see any connection between it and "the value" of the property at the time it is being used for the public?

On page 6, the report reads: "The subject is clearly in the development stage, and any conclusions reached at the present time must be considered as tentative," and, on same page, it again reads:

"It is recognized, however, that the whole subject is in a development stage, and while your Committee has been guided largely by the decisions of the higher Courts and public service commissions, it recommends what seem to be sound views and desirable changes in practice, even though not wholly in accord with such decisions."

The question is here presented as to the value for any purpose of views which admittedly are but tentative, and which, in addition, are concededly in violation of the law as declared and expounded by our highest Courts.

It is to be said in conclusion that though the report as a whole clearly indicates that it was written with reference primarily to such public service corporations as water and gas plants, it nevertheless contains much that is of value in the valuation of the property of common carriers. It discloses much thought on and consideration of the valuation problem, and contains many suggestions that will

Mr. Churchill.

be helpful in the solution of this problem. It is so fundamentally wrong, however, in the theory on which it is prepared, that as a whole it has no value for those dealing with the property of carriers. As it is written, a careful and exact following of its recommendations would not result in any one knowing "the value" of the property appraised. The report designedly and purposely excludes "value" as an end to be obtained, and substitutes therefor a sum, arrived at by arbitrary methods, to be used as "value for rate-making".

If it was desirable for such a sum to be found, the suggestions of the Committee as to methods for arriving at it would be entitled to due consideration, though, of course, it would have to be admitted that the fixing of this sum, whatever it should be, is more of a Governmental than an engineering problem. No purpose, however, could be served by a special value for rate-making as applied to carriers, because "the value" of their property when known will not solve the problem of rate-making, either for them or by them.

The Committee's report ignores (*a*) the requirement of the law that "value", without regard to the purpose of its use, be ascertained; (*b*) that the "value" when ascertained may be used for many other purposes than the regulation of rates; (*c*) that even in rate regulation it is only "the value" of the property that can be used; (*d*) that the protection of the Constitution extends to "the value" of the property; and (*e*) that when in support of a charge of confiscatory rates, a carrier presents the figures showing "the value" of its property, the Government cannot defend by showing a "value for rate-making" which is admittedly less than "the value" of the property.

For these reasons, and because the railroads of the country must be valued under the law, and not in accordance with any man's theories of what the law and the Constitution should be, the report should be referred back to the Committee to be harmonized with the law and the facts; and as this Committee was appointed "to formulate principles and methods for the valuation of railroad property and other public utilities", many portions of its present report should be revised, especially its Summary, Paragraphs No. 1, "Report Limited", etc.; No. 2, "General Principles"; No. 14, "Basis for Rate-Making"; No. 16, "Equal-Annual-Payment Method"; No. 19, "Appreciation"; and also the details of some other paragraphs. Further, these summary paragraphs should not be written as conclusions. On the other hand, as heretofore stated, the whole report should be changed so as to make it one of progress, from an engineering standpoint, and the Committee should be continued so that it may keep in touch with the reports of valuation, and with decisions of the Courts, as they are made from time to time, bringing to the attention of the members of the Society new features as they develop on this great subject, which, as the Committee states, is so clearly in the development stage.

M. H. BRINKLEY, ASSOC. M. AM. SOC. C. E. (by letter).—The Committee's report is a very comprehensive expression of valuation principles. The Equal-Annual-Payment Method of computing depreciation is both practical and logical. However, the decision of the Committee in regard to the use of depreciated value for rate-making may be supported by other considerations in addition to those given in the report. Mr. Brinkley.

In accordance with the agency theory of corporate control, the true relation existing between the public and the utility is that of principal and agent. The utility has a franchise which, in effect, is a contract between the two parties. In the very nature of the franchise, the utility has the right to do certain things which are ordinarily only vested in the State. The regulatory power of the State over rates follows naturally, because the utility is its agent.

The Courts have uniformly held that rates shall be reasonable, taking into consideration the value of the property. By "value" is not meant capitalized income, for if value is based on rates and rates on value, rates are always reasonable. Being denied the use of capitalized income, which is the real value of the unregulated property, the use of the actual investment or investment cost is the next step. The use of investment cost follows naturally from the agency theory.

If the utility is the agent of the public and the regulatory power is exercised from the beginning, the actual investment is the value on which rates can be predicated. However, the investment cost is not often obtainable, and, in lieu thereof, physical value is taken, as the investment was the physical value when the utility was new.

The physical value will have depreciated with the age of the utility. It must be assumed, however, that repayments have been made, either by unwarranted dividends or through earnings being placed in additions and betterments.

Practically all the utilities in the past have been unregulated. The adequacy of rates for the repayment of capital on account of depreciation has been under their control. If they have not been repaid, is it the fault of the public? The last paragraph of the Committee's quotation from the Knoxville water case is very apt in this connection.

If dividends by good management could not have been sufficient for repayment of lost value through depreciation, then the stockholders have simply made an unfortunate investment, as other utilities are not condemned for paying excessive dividends. Unearned dividends cannot be capitalized, and this applies to dividends which are insufficient to repay loss due to depreciation.

It has been stated that depreciation is a liability of the stockholders. Then, if true, replacements should be paid for out of dividends. Permanent depreciation has been called deferred maintenance, but the company will never again need to go to the expense of placing the property

Mr. Brinkley.

in 100% condition, because the life of all items is not the same. In past years there has been depreciation without any corresponding maintenance.

The simplest illustration of value is sales value, or value in the markets of the world. In the sale value of any object or unregulated property, the condition or depreciation is taken into account. The revenue being derived might also be considered, but the foundation value or physical value is the depreciated or present value. In the present value, the appreciation of some elements, as well as the depreciation of others, is accounted for. Justice is certainly done if they are both considered.

In basing rates on present value, the utility is not simply viewed as an aggregation of inert physical elements which have depreciated with age. On the other hand, it is seen as an operating property which is yearly taking out of earnings amounts sufficient to repay capital for depreciation. It is repaying this uniformly with the least drain on the earnings of the utility. The Straight-Line Method does not do this, as shown by the Committee, as the earnings have to be larger in the earlier than in the later years; but the Equal-Annual-Payment Method brings about the repayment in the most efficient manner, because it takes place on a compound-interest curve. The earnings on the remaining investment are the complements of the yearly repayments, and their total amounts will be the same each year if the interest rates are the same. As it happens, the actual depreciation takes place approximately in the same way. It is small in the early years of the life of the items and increases yearly to the end. It has been stated that, on account of the fact that railway companies are in 100% operating efficiency, they should be valued at cost of reproduction, which in this case means reproduction value as generally used. Does 100% operating efficiency mean that a utility structure is from 0 to 100% more valuable than one of the same age, life, and original cost which is being used for other than public service purposes? If there is any such additional value, it is a non-physical or intangible value, due to its use by a utility. In that case, however, the non-physical value would always amount to the actual depreciation. This value would then be greater in an old structure than in a new one, which is absurd.

In regard to operating efficiency, it must also be stated that we are not making a valuation of the efficient management of the owners, but are estimating the actual physical value of the property, and, in finding the physical value, the operating efficiency cannot be considered. Operating efficiency should only be considered in the rate of return allowed on the investment. It should there be given due consideration.

The advoctes of reproduction value for rate-making purposes contend that it is the nearest approach to original investment; but they fail to take into account that the property has been operating since

originally constructed, and, in finding the investment, the average earnings to date should be considered as the property has depreciated while producing earnings. This is on the basis of the agency theory exclusively. On this basis, if right of way for railways is included at present values, its increase in value from original cost should be counted as earnings. If this is not done, it should be placed at original cost. Mr. Brinkley.

If right-of-way multiples for railways are used, as advocated by the Committee, they are being taken on values which are in great part produced by the existence of the road itself. It would be very difficult to calculate what the values would be if the railway did not exist. The only alternative seems to be to take it no higher than the present market value of adjoining land, as this is the only measure of value which we have. However, if the actual cost was greater than the present market value, it should be given due consideration.

In the foregoing discussion, the views set forth are only meant to apply to a property in which no depreciation fund exists. For a property which has a depreciation fund, the writer can only express agreement with the views so ably set forth by C. E. Grunsky, M. Am. Soc. C. E., in his paper entitled "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates."* In that paper he showed that, if a depreciation fund existed of an amount equal to the actual depreciation of the property, the reproduction value should be taken as the value for rate-making purposes. This is shown to be consistent with the use of present value, where no depreciation fund exists, as was shown by the writer in his discussion† of the paper by William J. Wilgus, M. Am. Soc. C. E., on "Physical Valuation of Railroads."

For a property with no depreciation fund, reproduction value could be used with the same result on earnings and rates as the use of present value, if the cost of replacements to the extent of interest on the depreciation is paid out of dividends. The net return to the stockholders is the same in the two cases, but the rate of return is different on the different values.

As stated by the Committee, development expense starts after the utility begins to operate. It cannot be considered in reproduction value new, because it is not incurred during construction, but during the early years of the plant's life, after it begins to depreciate. To a certain extent, it offsets depreciation in calculating present value. It could be included by allowing liberal value for interest and commissions.

When one contemplates the rate regulation problems, and the adjustment of rates with physical valuation, as the main basis, anything but an approximate solution for competitive utilities, such as railways,

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 770.

† *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 244.

Mr. Brinkley.

seems hopeless. Under the circumstances, public ownership of railways and other utilities appears to be inevitable at some time in the future. If it comes, it will not be on account of the possibility of lower rates, but the desire of the public to have better control of public agencies, whatever the cost.

Mr. Stone.

H. M. STONE, M. AM. SOC. C. E. (by letter).—The title of the report as submitted is "Valuation for the Purpose of Rate-Making", while the Committee appears to have been appointed "to formulate principles and methods for the valuation of railroad property and other public utilities".

It should be distinctly borne in mind that methods of estimating depreciation on gas, water, and electric light plants, or similar public utilities, are not the same as those used for estimating on railroads. The railroad property is in the open, can be readily examined, and is not allowed to run until it is worn out, but is constantly in the process of renewal. In gas, water, and electric light plants, there may be no competition; they serve all the requirements of a community, quite in contrast to railroads which have to furnish equal service at the same price, and in nearly all cases are strongly competitive.

Railroad rates are not based on the value of the property used to render the service, and it is well understood that such rates are based, or substantially depend, on many things, among which may be mentioned: (*a*) value of service; (*b*) competition between carriers, localities, and commodities; and (*c*) cost of service. Carriers between competing points must maintain the same rates, and no shipper, locality, or class of traffic can be given any undue advantage or be subjected to any undue disadvantage. Rates, from different sources of production of the same or like commodities to the markets therefor or to the places where the same are consumed, must necessarily bear a certain relation to each other.

The report of the Special Committee ignores all the considerations on which railroad rates are, in fact, based, and erroneously assumes that they are, or can be, based on the value of railroad property.

The report is only a discussion of valuation "for the purpose of rate-making" (page 70). It asserts in substance that the depreciated value of the property should be the basis for rate-making, and proceeds on the theory that the depreciation allowance is in fact a repayment in installments by the rate-payer to the corporation of a part of the investment in particular items of property. It seems to be the opinion of the Committee that the sum said to be so repaid should not thereafter appear in the valuation of such items.

Applied to the valuation of a public service plant, like a waterworks, owned by a municipality, or enjoying an absolute monopoly, the report contains suggestions that may be useful in the work of

appraisal or in determining what rates, under the circumstances, ought to be fixed, but it is utterly inadequate as a guide for the work of ascertaining the value of railroad property, and the writer believes that certain statements therein are imperfect and misleading. Mr. Stone.

The Act of Congress directing the Commission to value railroad properties does not specify the purpose of the valuation, and any assumption that it is "valuation for the purpose of rate-making" is not justified.

It is a mistake to assume that either the cost of reproduction new or the cost of reproduction less depreciation may be used as a measure of, or sole guide to, the value of railroad property. The Valuation Act requires the Commission to investigate and report the value of all property owned or used by the carrier, and directs it to ascertain and report in detail, as to each piece of property, certain facts which are, or may be considered as, evidence bearing on value, among which are: (*a*), the original cost to date; (*b*), the cost of reproduction new; (*c*), the cost of reproduction less depreciation; (*d*), other values and elements of value; (*e*), the history and organization of the present and of any previous corporation operating the property; (*f*), any increases or decreases of stocks, bonds, or other securities; (*g*), the moneys received by reason of any issues of stocks, bonds, or other securities; (*h*), the syndicating, banking, and other financial arrangements under which issues were made, and the expense thereof; (*i*), on the net and gross earnings of such corporations; (*j*), the expenditure of all moneys and the purposes for which they were expended.

The writer is of the opinion that no one of these items of evidence is to be taken as the measure of the value of railroad property, but that it is expected that the Commission will take all into account and give to each its proper weight in the ascertainment of the value of the property.

The report (page 6) proceeds on the theory that "The valuation is for the purpose of determining rates which shall be a limitation of charges to those which will give a fair return and no more". Rates may be fair and reasonable and still be high enough to yield a substantial surplus after the payment of operating expenses, including maintenance and proper allowances for depreciation, and after the payment of a fair return on the full value of the property. As a general rule, railroad rates ought to be high enough to permit the accumulation of such a surplus in order to establish and maintain credit. In some instances, however, reasonable rates may not be sufficient to yield a fair, or any, return on the values of the property; but such instances are rare, and are usually due to peculiar or temporary conditions. The value of railroad property is not a means for the ascertainment of the reasonableness of rates, and, as a general rule, is not used as a guide by which rates are fixed. A railroad company is

Mr. Stone.

entitled to a fair return on the value of the property used in the public service, if that return can be earned by the application of rates which are not unreasonably high, and it cannot be compelled, without a violation of constitutional rights, to put in rates so unreasonably low that confiscation will result. The only cases in which the value of railroad property or the rate of return thereon is of importance as affecting rates are those in which it is claimed that Governmental authority has prescribed rates which are confiscatory.

It is always to be borne in mind that a rate may be sufficiently high to withstand attack on the ground that it is confiscatory, and yet be so low as to be unreasonable and contrary to a wise public policy.

On page 7 of the report it is stated in substance that

"Justice and equity require that in any regulation of rates fixing the amount which may be earned by a public service corporation there shall be taken into consideration two distinct features:

"First, the annual return covering interest and profit to which the corporation is entitled for the use of its capital, having in view the risks incidental to the investment.

"Second, an allowance sufficient to provide for the net depreciation in the value of all the items of physical property, whether resulting from decay, wear and tear, or other cause, the amount of such depreciation allowance to be sufficient to amortize all such items of property by the time they cease to have value."

It is respectfully submitted that this statement is inaccurate, and that the allowances are insufficient, because these allowances do not provide for any margin of safety or the creation of any surplus to serve as a basis of credit. It is in the interest of the public that the credit of the carriers be sufficient to enable them to procure funds necessary to provide facilities to meet the increasing demands for service.

Depreciation, as set forth in the report, is impractical, and almost wholly inapplicable to railroads. There are no tables of mortality that will give any reasonable results, nor would it be possible to make such tables for the bulk of the items of railroad property, nor are they a factor in the determination of rates.

The maintenance department of a railroad, at the close of a year, knows very closely whether or not there has been enough expended on the property to keep it up to its adopted standard. Any system of accounting by the use of mortality tables is relatively worthless as compared with actual knowledge as to the main facts in connection with the maintenance of a property, which knowledge is in the possession of those only who have had the maintenance in hand. The same holds true of equipment, that is, those having charge of the maintenance of equipment of a road know very definitely whether or not the equipment is kept up from year to year.

Mr. Stone.

The so-called depreciation is no more or less than the amount necessary for maintenance, and that amount can be known only by knowing the facts in the case for each property; it can never be ascertained by the use of mortality tables, which would introduce a mass of fallacious accuracy that would require continual adjustment.

Depreciation is not an amount paid back to the investor, which should no longer appear in the valuation, but it is the amount that it is necessary to spend to keep the investment intact, and, therefore, in any valuation made to indicate on what amount a railroad should be allowed to earn a return, it has no place whatever.

There are some instances where, as a matter of policy, a company should provide for some extraordinary renewal which it is apparent is approaching, by some special arrangement that will not throw the burden of this renewal into a single year; but that is a matter of expediency on the part of the railroad, and is not a matter of valuation.

On page 10 of the report it is in substance suggested that the cost of all obsolete items be deducted.

Without here expressing an opinion as to whether or not it is generally right to take into account obsolescence in the ascertainment of cost of reproduction less depreciation, the writer suggests that it is clear that the Valuation Act does not require obsolescence to be taken into account in the ascertainment of the cost of reproduction less depreciation. The depreciation there specified is to be ascertained by a comparison of the state of repair or physical condition of the item of property at the date as of which the valuation is made, compared with its condition when new.

On page 13 of the report it is suggested that, "An engineer in ascertaining a value for rate-making must take into account whether or not the property, although owned by the corporation, is in use."

It is not necessary that all railroad property must be in actual use on the date as of which the valuation is made, but there should be included all property acquired and held by the company, which it is expected will be used in the future. For example, in the development of a terminal in a large city, several years may be required in order to secure the needed land and to perfect arrangements with public authorities. Property acquired for immediate use and actually being prepared therefor at the date the valuation is made certainly ought to be included. It may be difficult to state a general rule to cover this point, but it is certainly unfair to make "actual present use" the test.

The attempt to segregate land into different classes, according to its use or proposed use, cannot properly enter into a just valuation. The owners of railroad property have decided that the acquirement of certain lands was a proper course to take. To treat land donated by the Government as of different value than other land, because of

Mr. Stone.

such donation, is unjust. As a rule, such land has been paid for several times over through the medium of special service rendered by the railroad to the Government. It cannot be said that some arbitrary strip of land has one value, and that another strip, possibly immediately adjoining, has a different value, basing such value on the apparent or present use.

On page 15 of the report it is suggested, "that valuations should be based upon the physical conditions existing at the time the various portions of the property were built, but at the prices prevailing at or near the time of the valuation."

The Special Committee is opposed to including in the estimated reproduction cost that of laying gas mains or water pipes in a street the expense of tearing up and replacing pavement which did not exist at the time the mains or pipes were laid, and seems to hold that such expense is no part of the present value of the mains or pipes, and apparently for that reason reaches the conclusion that the same should not be included in the estimated reproduction cost. It seems to the writer that this results from assuming that every figure which is used as "evidence of value" must be the same as that which "expresses the value". There is no doubt that in case of present reproduction the pavement would have to be torn up and replaced. Reproduction cost is not synonymous with value, but merely one fact or item of evidence to be used in ascertaining value. The engineering conception of reproduction should be followed throughout, and should not be modified to correspond with varying conceptions of value or to meet the supposed requirements of justice in particular instances. It is for the tribunal charged with the duty of finally ascertaining the value to give to the reproduction cost figure and to each of the other established facts such weight as they are entitled to in the light of all the evidence.

Again, on page 17 of the report, it is said:

"If after a pipe has been laid in a street new grades were adopted, the reproduction cost of the pipe should be estimated on the basis of the original grades, and if the regrading required a raising or lowering of the pipe already laid, the cost of such work, if not charged against the rate-payers as a part of the current expenses, should be included in the reproduction cost."

This statement confuses original cost with the conception of reproduction cost. If the property were presently to be reproduced, the cost thereof might not be affected by the fact that pipes had been raised or lowered since original construction, and it is not perceived how the source of funds expended for laying or raising or lowering the pipes would affect the present cost of reproduction.

On page 31 it is said:

"The Committee has already suggested that many principles and methods applicable to a normal property are not applicable to a 'losing

venture'. For instance, the 'losing venture' is not entitled to what would otherwise be a fair return on the fair value of the property. It has to be recognized in such a case that the investor must accept the resulting losses and such rates as the services rendered are worth, and to be recognized in such a case that the investor must accept the resulting earnings and not on other methods of valuation." Mr. Stone.

Undoubtedly, a railroad company cannot maintain rates that are unreasonably high merely because its enterprise is not a financial success, but it is difficult, even in the case of a "losing venture", to see how rates or revenue can be used logically to determine value, if that value is to be used as a basis for rates. The conception of the Committee seems to be that the rates are to be fixed at what the services are worth and that value may be based on earnings derived from such rates. This idea ought not be confined to "losing ventures". A railroad property so located, constructed, and operated that, at rates measuring the fair value of the service, it can earn an ample surplus, after the payment of operating expenses, together with a fair return on value, is certainly worth more than the cost of reproduction less depreciation, and such properties are usually worth more than the undiminished cost of reproduction new. It is unreasonable and unfair to limit the value of such a property to "The Depreciated Value" (page 72), and then to fix rates so low as to be sufficient only to pay return on such value.

The writer, of course, recognizes the fact that a railroad may be located and built so that it may be worth even less than cost of reproduction less depreciation, but such instances are unusual.

On page 32, it is said:

"A depreciation allowance is, in effect, a payment from the ratepayer to the corporation of a part of its investment, and such part of the investment as has thus been repaid should not appear in subsequent valuations of the property."

It is always proper to include in operating expenses a sum sufficient to maintain each element of the property in proper repair and to replace its worn out parts. This "depreciation allowance" is not a payment to the corporation of a part of its investment in any proper sense, but is a just part of the operating expenses.

On page 41, it is said:

"There is a fundamental objection to depending upon the personal judgment of appraisers, as this method determines only the total depreciation of the property and not the amount of the depreciation allowance which the corporation is entitled to earn, unless it is to be assumed that the difference in the amount at which the property is appraised from time to time furnishes a measure of the amount of depreciation which should be allowed during the period between such appraisals. It is obvious that very erratic results would be obtained by such a method, especially if different persons acted as appraisers in different years."

Mr. Stone.

This statement seems to fail to make a distinction between the ascertainment of the value of the property in its present condition and the amount of money required to keep up the property and to renew its worn out parts. The value of the property is one thing and the amount of money necessarily included in operating expenses to repair it and to renew its parts is another and entirely different thing—one is the appraisal of the value and the other is the ascertainment of an element of operating expenses.

On page 50, under the caption, "Appreciation", the report seems to indicate that it is the view of the Committee that railroad companies are not entitled to the increase in value of their right-of-way and terminal lands; it is said that such lands "sometimes increase in value so rapidly that the question arises as to the justice of basing rates upon the present value of the land rather than its original cost."

The writer understands it to be settled by the highest authority that, if it can be earned on reasonable rates, a railroad company is entitled to a full and fair return on the value of the property at the time it is used in the public service. It is known to everybody at all familiar with railroad affairs that, notwithstanding enormous increases in value of terminal lands, rates have constantly decreased. It is not necessary to confiscate the increase in value in order to have reasonable rates.

It is stated in the report:

"The Courts have recognized that the corporation is entitled to earn from the public the sum necessary to offset the depreciation in the value of its structural property; similarly, the public is entitled to receive from the corporation due recognition of the increase in value of those portions of its property which appreciate in value. The principle involved in the two cases is the same, and there is no reason to think that its application to both would not be supported by the higher Courts."

"The sum necessary to offset depreciation" is just as plainly an operating expense as the cost of labor or fuel required to operate the locomotives. The present value of the terminal lands of a terminal company is property, and the company is entitled to pay for its use in public service and is not limited to a return on that portion of the value which existed at the time of acquisition. Railroad property is private property, subject to regulation to prevent excessive charges and discrimination. As the writer understands the suggestions of the Committee, it is that the appreciation in the value of land be considered as an offset and payments of depreciation of other parts of the property. It is certain that the company cannot use the increase of terminal land value directly to maintain its roadbed or to repair or replace worn out equipment or structures. The appraisal of land at present increased value and the allowance of a return thereon to take care of depreciation (page 50) not allowed for in operating ex-

penses—as it should be—is unfair, and amounts to confiscation of such return or increased value. Mr. Stone.

On page 67, it is stated:

"Embankments and the slopes of cuttings may become more stable on account of the growth of grass and weeds, and may therefore be considered to be more valuable, but such value as this, which is not the result of expenditure by the corporation, should have no place in the valuation of the property."

This ignores the well-settled proposition that the railroad company is entitled to full present value of its property. The principle on which this suggestion rests would deny to the company the value of lands and other property granted or donated as an inducement for the building of the road; it would deny to the company the value of all property created out of surplus earnings; it would deny to the company the increase in value of wooden structures, due to the rise in price of lumber. In short, it would leave it within Governmental power to limit the company's earnings to a sum sufficient to pay a reasonable rate only on the money actually contributed directly by owners to create the property, and this without any guaranty of any return whatsoever on such sums.

S. WHINERY, M. AM. SOC. C. E.—This report is confined mainly to the question of valuations for rate-making purposes, and deals with a number of factors under the general head of depreciation. Mr. Whinery.

To the speaker's mind, it is a serious question whether the use of this word, depreciation, to cover a number of separate elements or factors, as is now the practice of engineers, and to some extent of the Courts, is necessary or wise, especially in so far as discussions or negotiations with public officials and the public at large are involved.

The careful observer, in these times of business and industrial agitation and confusion, cannot but note that no small part of the current misunderstanding, dissent, and distrust has its roots in the failure of different classes of society to understand each other. This is especially true as regards the ability of the business community and the public at large to grasp and appreciate the views and statements of technical men and the doctrinaires. This is often due not so much to the existence of really conflicting views, as to the fact that these views are not presented in language and terms that all understand alike. This applies to some extent to the technical forms of thought and expression used by the engineer.

In professional investigations and intercourse among themselves, it is entirely proper that engineers should resort to such technical terms as have come to be recognized as having an accepted meaning by them, but would it not be better and wiser if, in communicating with those outside the Profession, and in dealing with public and semi-public matters, they would confine their professional vocabulary,

Mr. Whinery.

as much as possible, to such words and to such meanings of those words, as are recognized and understood by the public?

Take, for instance, this word, depreciation. Its ordinary meaning is loss or decrease of value or of utility; but, as engineers, we have apparently read into it, possibly unintentionally if not unconciously, meanings that are, stricting speaking, quite foreign to it.

Thus, an annuity, the real purpose of which is to create a fund to repay capital at a stated time, is not equivalent to, and may not be a correct measure of, depreciation in the primary meaning of that word. In the case of public service contracts the annuity or sinking fund should logically mature at the time the contract expires, without regard to the life of the plant. Again, cost of maintenance is not depreciation but its antithesis—a provision for preventing depreciation.

The fact is that engineers themselves are somewhat at sea as to the definition and use of the word, and differ quite widely in their methods of dealing with the subject and in the several elements which they think should be included under that general head.

The Committee would render a valuable service to the Society and to the Profession, if it would give this matter careful consideration, recommend an acceptable definition of depreciation, and limit the cost-factors that may properly be included under that name.

In the equal-annual-payment plan proposed by the Committee under the general head of depreciation, the elements that make up the annual payment are not very clearly stated. Apparently, they include a sinking-fund payment to repay capital, interest charge on the capital invested, some part, at least, of the cost of repairs and maintenance, and possibly some provision for betterments. The result arrived at by this scheme may be wholly fair and reasonable for rate-making purposes, but the non-professional man will hardly be able, without more careful study than he is likely to devote to it, to understand how the annual payment is made up, and will be likely to look on it, or any other rigid depreciation formula dealing with several elements, with more or less mystification and distrust. There is evidence that not a few engineers who have given the subject no little thought, seem to be in a like frame of mind.

It may be argued with much reason that the whole subject of negotiating and establishing rates may be handled satisfactorily without any reference to depreciation, in the complicated sense in which it has come to be sometimes used.

A franchise for a public service is usually for a long term of years. Its purpose is to secure for the public a stated quantity and quality of service during its life. This requires the investment of a sufficient amount of capital to supply that service in a satisfactory manner. The party supplying the service is entitled to a fair and reasonable compensation therefor, and the object of rate-making is to determine

what that compensation should be. Now any intelligent public official, business man, or citizen knows, or may be readily shown, that a fair and reasonable rate must be made up of certain elements, the principal ones being: Interest on capital invested, operating expenses, repair and maintenance of plant, a liberal allowance for contingencies, a fair profit above ordinary interest, and, in the end, the return of the capital invested. Mr. Whinery.

There is here no mention of depreciation, nor is it necessary. The charge for maintenance takes its place. Obviously, the property must be maintained from the beginning to the end of the franchise in a condition to furnish properly the service required. If this be done satisfactorily, there can be no functional depreciation, or, at least, none from any proper point of view of the party receiving and paying for the service. The intrinsic or market value of the plant may fluctuate from time to time, as machinery is worn out and replaced, but these fluctuations do not affect the value of the plant for the purpose for which it was provided, nor call for any change in the rate of compensation, and they do not, therefore, interest the party receiving the service.

Notwithstanding, however, that the plant must be maintained in a condition to supply the service up to the very end of the contract time, its intrinsic or market value, at the end of the period, will be less than its original cost, and the difference between these two sums is depreciation in the sense in which the speaker would suggest that the word be used. Obviously, in the case of a perpetual franchise, there would never be depreciation in that sense, but the charge for maintenance would be sufficient to keep the property up to the necessary standard of adequacy.

Of course, the person, company, or engineer negotiating to supply the service may use such depreciation formula and other methods and devices as he thinks proper in computing the cost of maintenance, and must be prepared to translate his conclusions into facts and arguments comprehensible to the business man, but in all other respects the transaction will rest on plain business principles and practices which the average business man will readily understand.

The Committee seems to hold that the rate charged should include some provision for betterments and improvements. It will be difficult to convince the alert, clear-thinking, business man that such a provision is just. He will reason that if the equipment as originally designed and provided is adequate to supply the service contracted for, and is thereafter properly maintained, the cost of such maintenance being provided for in the rate, no additional capital investment will be needed to meet the full requirements of the contract; and that if additional or more expensive service becomes necessary or is wanted, supplemental contracts or franchises in which the question

Mr. Whinery.

of additional capitalization and, if necessary, a proper readjustment of rates can be considered, would be the proper and business-like way to deal with the matter; and that, as to improvements, they will not usually be made unless they promise to decrease the cost of production, and consequently increase the net profits to an extent that will make the improvements, in the opinion of the contractor, advantageous to him, under which conditions the party receiving and paying for the service should not be called on to bear their cost. In any event, it would be difficult to convince him that these items have any logical connection with depreciation.

What has been said assumes that we are starting with a new project and plant, the cost of which (*i. e.*, the capitalization) may be ascertained and demonstrated with reasonable accuracy. In the majority of cases, however, where the question of rate regulation comes up, an existing plant is involved, and the question of its value, as indicating the amount of capital invested, must be determined by an appraisal, and it may be said that in all such appraisals the factor of depreciation is so important as to be controlling; but, is this true? Does not the engineer or appraiser of wide knowledge and experience actually base his judgment on concrete facts and conditions rather than on deductions from any theory of depreciation?

In judging of the value of a machine or a system of machines, the real question is not what is its age or what work has it already done, but what work is it capable of doing in the future? We want to determine its expectancy of useful life from this time on, rather than its fair average expectancy of life when new, in order that we may subtract its present age from its estimated total life and assume the remainder as its future potential useful life. Its history may be useful to us in arriving at conclusions, but such evidence is of secondary value. It is useful to know that the average life of a certain kind of machine is, say, 20 years, but we are likely to make serious errors if we use that figure as a measure of the life of all such machines. That life should be measured in units of work and endurance rather than in units of time. This is all the more true because the element of proper maintenance is very important. We all know that, of two machines, duplicates in all respects, difference in care and maintenance under the same work may make the useful life of the one 100% longer than that of the other. How then can we be justified in applying any rigid rules of depreciation based on assumed or average life to individual machines? Must not the value of each be judged on the present evidence of its probable efficiency and durability, under the conditions of service to which it is likely to be subjected? We must remember, too, that unforeseen conditions of inadequacy or obsolescence may appear at any time, in defiance of all formulas,

and the weight to be given to their probability must be purely a matter of good judgment. Mr. Whinery.

The speaker's argument is not, however, that the appraiser may not consider the bearing of any theory or formula of depreciation, or any other data or evidence available, in arriving at the value of any machine or plant, though he believes the more experienced and capable a man becomes in appraisal work the less weight will he attach to theoretical or hypothetical considerations and the more will he rely on tangible practical evidence. The speaker, however, is convinced that reports of appraisals that are to go before non-professional men, such as public officials and business men, are not strengthened by refences to or discussions of complicated theories or rules of depreciation and conclusions that seem to be based thereon.

On the whole, it seems to the speaker that engineers have built up around this word, depreciation, in so far at least as it is concerned in rate-making, a complicated and unnecessary body of theory and speculation, not very useful to themselves, but well calculated to be a stumbling block in their dealings with the public.

PHILIP W. HENRY, M. AM. SOC. C. E.—This report is an interesting and valuable document, and the Committee is to be congratulated on the thorough manner in which it has dealt with this important subject, covering as it does so many of the elements which enter into this problem. The discussion on depreciation, however, is not clear, and the speaker is at a loss to know whether the Committee intends to express the opinion that, after a depreciation reserve is set aside, the investor is entitled to a full return only on the original investment less depreciation reserve, or whether he is entitled to a full return on the original investment. As various statements on this point are apparently not in accord with one another, it would seem that the Committee should express itself with greater exactness, for it must be remembered that any report adopted by this Committee will carry great weight, not only among engineers who are more or less familiar with the principles of depreciation, but also among public service commissioners and others who may not have made a study of the subject and who, therefore, may be misled by the apparent discrepancies in the report. That the members of the Committee had clearly in their own minds conditions under which the investor is entitled to a return on his original investment, and other conditions under which he is entitled to a return only on the "remaining value of property", is not doubted by the speaker, but these different conditions should be presented with such simplicity, conciseness, and clearness as to leave no doubt in the mind of the reader, however unfamiliar he may have been heretofore with the elementary principles which govern depreciation. Mr. Henry.

Mr. Henry.

As stated by the Committee: "There is no subject connected with valuation about which there are more diverse views than those relating to depreciation." In addition to this difference of opinion which exists in regard to depreciation itself, there is also a difference of opinion as to whether the same method of depreciation should be used for private corporations, where investors alone are interested; for public service corporations, where rates are regulated by public service commissions; and for railroads, where an endeavor is being made to fix rates in accordance with physical valuation. In the speaker's opinion, the same method should be used in all cases, for depreciation is one of the elements necessary to present a full and clear statement of the condition of the property; and whether this full and clear statement is for the use of the investor or of the public service commission is immaterial. In order that the investor may know the true value of his shares of stock, he must know exactly the condition that his company is in, and unless depreciation is properly taken into account, he cannot have this full knowledge. The same is true of a public service corporation, for, in order to fix rates, it is essential to know the true earnings of the corporation, and such earnings cannot be known unless depreciation is properly cared for. Therefore, whether depreciation is set aside by a mining company, the operations of which will inevitably come to an end (say, in 20 years); or whether it is set aside by a public service corporation or a railroad (the operations of which will continue indefinitely), the principle is the same in each case, and the same method of depreciation should be used.

It will be admitted that an investor is entitled, not only to a reasonable annual return on his investment (when properly and intelligently made), but also to receive back his principal at any time, whether he receives it through the sale of his property to other parties, or whether, as in the case of an exhausted mine he receives it from a depreciation reserve which has been accumulated out of earnings, and which when the mine is exhausted (assuming no scrap value), just equals the amount of his original investment. Such depreciation reserve, when properly set aside, guarantees the integrity of the original investment, whether the money is invested in a mine or in a public service corporation. If in a mine, the investor alone is interested in knowing that his original investment is maintained at a constant value, and that the return he receives in dividends, whether 5, 10, or 50% annually, is really earned. If the money is invested in a public service corporation, not only is the investor interested, but also the general public, which, by the rates it pays for the services rendered by the corporation, is interested in knowing that the property is being maintained out of earnings at a constant value (thus assuring equally efficient service as the plant grows older) and that, in addition, there are earnings sufficient to provide a reasonable annual return on the

money originally invested. If the earnings are greater than are required for these two purposes, then the public may be justified in demanding a reduction of rates. If they are less than sufficient to maintain the property at a constant value and to pay a reasonable return on the money invested, it will be impossible for the corporation to obtain the new capital necessary to maintain the efficiency of the plant, and to make such additions as are necessary to take care of the increasing business. If, therefore, a public service commission or other authorized public body establishes a maximum annual return for a public service corporation, it is important that both the commission and the corporation should know that, after paying operating expenses, including the cost of ordinary repairs and small tools, there remain earnings sufficient to pay the authorized annual return on the original investment and set aside in the depreciation reserve each year a sum adequate to maintain the property at its original value. In other words, the amount standing at any time in the depreciation reserve, plus the value of the property at that time, should equal the original value of the property (original investment), neglecting the influence which appreciation and other elements may have on the problem so fully presented by the Committee. It must be borne in mind that in this discussion the speaker confines himself solely to depreciation, without reference to other features of the Committee's report. If it is possible to arrive at general principles governing depreciation, applicable to all classes of corporations, the application of such principles to a given corporation will be comparatively simple, due allowance then being made for the effect which other elements may have on the problem. Mr. Henry.

Strictly speaking, the only true way to set aside a sum each year for a depreciation reserve is to make each year a careful valuation of that portion of the property subject to depreciation, and the difference between the value thus established and that similarly established the previous year, is the amount which should be placed that year in the depreciation reserve. Manifestly, such yearly valuation is impracticable, and it has been generally agreed that the simplest method for determining the depreciation is to assume a life-period for each part of the plant subject to wear or obsolescence, and to set aside each year a certain sum based on such life-period. Whether the investor in the assumed public service corporation is entitled to the authorized annual return on the original value or on the remaining value depends entirely on the method used in setting aside the depreciation reserve. For purposes of simplifying the discussion, it will be assumed that the depreciation reserve is invested in outside securities, although the argument holds good in case it is invested again in the property, in betterments and additions or otherwise, earning the same rate of interest as if invested outside.

Mr. Henry.

If the depreciation reserve is maintained by the Sinking-Fund Method, by which the sum set aside each year, plus interest compounded annually, amounts at the end of the life-period to the original value, the stockholder is clearly entitled each year to his full return on the original investment. On the other hand, if the depreciation reserve is set aside by the Equal-Annual-Payment Method, or by the Straight-Line Method, by which certain sums are set aside each year, totaling (without interest) the original value at the end of the life-period, the stockholder is clearly not entitled to a return on the original value, as he either receives directly the interest on securities in which the depreciation reserve is invested, or else the property receives it as an amount available for dividends.

To make this clear Table 18 has been prepared, assuming that the property has a 20-year life-period, valued when new at $100; authorized annual return, for example, of 7%; annual interest of 7%, for example, on funds standing in the depreciation reserve, such percentage being compounded annually to the depreciation reserve in the Sinking-Fund Method; but, in the other two methods, the interest being paid out each year either directly to the investor or to the property available for dividends.

TABLE 18.

	Sinking-Fund Method.			Equal-Annual-Payment Method.		Straight-Line Method.	
End of year.	Amount set aside each year for depreciation reserve.	Interest at 7% compounded annually.	Total yearly amount to depreciation reserve.	Total yearly amount to depreciation reserve.	Interest at 7% paid out each year to investor.	Total yearly amount to depreciation reserve.	Interest at 7% paid out each year to investor.
1	$2.44	$0.00	$2.44	$2.44	$0.00	$5.00	$0.00
2	2.44	0.17	2.61	2.61	0.17	5.00	0.35

19	2.44	5.81	8.25	8.25	5.81	5.00	6.30
20	2.44	6.38	8.82	8.82	6.38	6.00	6.65
Total.	$48.80	$51.20	$100.00	$100.00	$51.20	$100.00	$66.50

Mr. Henry.

From Table 18, it is evident that, under the Sinking-Fund Method, the investor is entitled each year to a return of 7% on the original value of $100. Under the other two methods, he is entitled to less than 7% on the original value, which apparently is what the Committee means by "the corporation must accept a return upon the depreciated value of such property". Referring again to Table 18, in the twelfth year, for example, under the Equal-Annual-Payment Method, the investor received $2.69 from the securities in which the depreciation reserve is invested (whether inside or outside of the property), and is, therefore, entitled to receive only $4.31 ($7.00 less $2.69) from the property itself, which is 4.31% on the original value of $100. In the twelfth year, under the Straight-Line Method, the investor receives $3.85 from the securities in which the depreciation reserve is invested, and is, therefore, entitled to receive only $3.15 ($7.00 less $3.85) from the property itself, which is 3.85% on the original value of $100.

From this comparison of methods it seems to the speaker that the Sinking-Fund Method is the simplest and best, but as (to use the words of the Committee) "the use of the words Sinking Fund appears to have misled some Courts and commissions", it may be better perhaps to call this method, as above exemplified, the Straight-Line-Interest Method, which describes the method of putting aside in the depreciation reserve an equal amount each year (2.44% as in Table 18) out of earnings, and adding to it the interest on the total amount in the depreciation reserve, whether it is invested in outside securities or in the property as betterments and additions, or otherwise. As it is difficult to find safe outside investments returning more than 4%, it is preferable, generally speaking, to invest the depreciation reserve in the property itself, where it will earn the same annual return as the original investment.

From the foregoing, as well as from the report of the Committee, it is evident that depreciation is not susceptible of exact mathematical treatment, inasmuch as it is based on the life-period of the various parts making up the property, or on the condition of each part in any one year. As both the life-period and the condition of any property or of its component parts are purely estimates, on which no two engineers will agree in detail, it is evident that in setting aside a depreciation reserve, refinement is unnecessary, and the method which will best accord with present methods of accounting and which can be most easily applied is the one which should be adopted. No matter what method is adopted, and no matter how conscientiously and intelligently it is applied, it is quite likely that an experience of 5 or 10 years will show that the depreciation reserve is too great or too small, and, therefore, that a change should be made in the percentage set aside each year. For this reason it may be advisable at convenient periods to make a valuation of those parts of the property susceptible to depreciation, in

Mr. Henry.

order to know whether or not the amount in the depreciation reserve equals the original value less the present value, as it should do—leaving out of consideration appreciation and all other elements which may affect the problem.

Depreciation reserve, as an account on the balance sheet, may stand alone as a liability on the credit side, or it may be shown on the debit side as a deduction from the asset, plant account. The speaker prefers the former method. No matter how it is shown on the books, or whether or not it is invested in outside securities, it should be reserved strictly for the purpose for which it has been established, and should never be considered as applicable to dividends. If it is found to be larger than conditions warrant, the amount set aside each year may be diminished or omitted altogether for a few years; if too small, the amount set aside each year may be increased.

As a matter of bookkeeping, at the end of each year profit and loss will be charged, and depreciation reserve credited, by the amount to be set aside, on each item of plant account, figuring the same percentage each year on each item, depending on the life-period and the rate of interest borne by the funds in the depreciation reserve. The depreciation reserve will also be credited at the end of each year with the interest earned during the year by the securities in which it has been invested. If it is merely a book account, and the funds have been used in the business for betterments and additions or otherwise, the depreciation reserve will be credited by interest on its average balance for the year, figured at the same rate which is being paid on the original investment, or 7% in the case which has been assumed.

On the debit side of the balance sheet, as an asset, will be found an amount exactly balancing, as an aggregate, the depreciation reserve as a liability on the credit side. If the depreciation reserve is invested in outside securities, the account on the debit side may be called "securities, reserve fund for depreciation". If the depreciation reserve is invested again in the property, it will be found, at the end of the year, that on the debit side certain assets, such as betterments and additions, accounts receivable, cash, etc., will be greater, as a total, by the exact total amount added that year to the depreciation reserve. During the year, from time to time, the depreciation reserve may be charged and cash credited (if a cash transaction) for any replacements, such as the purchase of a new engine to take the place of one which has been worn out or become obsolete; or these replacements during the year may be carried in a replacement account, and at the end of each year, the total of such account will be charged off to the depreciation reserve.

Under the Straight-Line-Interest Method (practically the Sinking-Fund Method), applied as already outlined, no question arises as to whether or not the investor is entitled to a full return on the original value of the property or only on the remaining value, as it does under

the Equal-Annual-Payment and Straight-Line Methods—thus making the latter two methods more difficult to apply. Another advantage of the Straight-Line-Interest Method is that the accounting is much simplified, and the only problem—not an easy one, however—is to establish the life-period of each item entering into plant account. Mr. Henry.

CHARLES HANSEL, M. AM. SOC. C. E.*—The Special Committee of the Society appointed under the resolution set forth on page 102 of the February, 1911, *Proceedings,* was instructed as follows: Mr. Hansel.

"*Resolved,* That a Special Committee of seven be appointed by the Board of Direction to formulate principles and methods for the valuation of railroad property and other public utilities, and to report to the Society at the next Annual Convention."

This resolution was adopted unanimously at the Annual Meeting of the Society on January 18th, 1911. It was offered by the speaker after he had stated that, in all the papers submitted on the subject of valuation of public utilities, there had been no definite outline of the proper principles and methods to be pursued in the doing of the engineering work necessary to the enumeration and valuation of the various physical elements, and that the papers and discussions were confined principally to questions of law and economics.

In offering the resolution, the speaker felt that it was clearly understood by the members present that, as an engineering body, the Society should take up the question of valuation as it relates to the gathering and compilation of engineering data. The title of the Committee's report, "Valuation for the Purposes of Rate-Making", does not appear in the resolution, either in precise language or in terms. The report deals mainly with legal and economic questions, devoting some 47 pages to the subject of depreciation; 13½ pages to land; 2½ pages to appreciation; and about ½ page to adaptation. There is no part of the report which deals with the problems attendant upon the gathering of field data. It touches upon preliminary expenses, engineering, general contingencies, and the like; all of which are provided for in the "Classification of Road and Equipment Account" of the Interstate Commerce Commission. It seems, therefore, unnecessary to discuss the propriety of including these items, as they have already been recognized and admitted by the highest accounting tribunal in the land.

It is always desirable that the engineer broaden his knowledge through the study of legal and economic questions. However, it appears to the speaker that the first chapter of the Committee's report should be devoted to the engineering questions involved rather than to a theoretical discussion of depreciation, amortization, and other accounting theories, which are important considerations of future accounting, and not aids to the determination of the present value of the physical elements or the whole property value of a corporation which

* This discussion was presented for Mr. Hansel by Carl Tombo, Assoc. M. Am. Soc. C. E.

Mr. Hansel.

has been in operation for some years. The speaker holds that there is no mathematical rule for determining depreciation, although it is quite proper that some empirical rule be adopted in accounting methods, so that the accrued replacement needs of the future may be anticipated.

In the determination of the present reasonable value of the segregated parts of a railroad or other public utility, we are not assisted by any formula of depreciation to be applied as an accounting method; and it is not likely that, in the valuation of any important railroad or other public utility, the depreciation for any purpose will be calculated by rule, but rather by investigation and observation.

The Chairman of the Committee has advised the speaker that, owing to the intricacies of the whole subject, "it was decided to take up first only one branch of the subject of valuation". It would be inferred from this statement that this report of the Committee is but one of several which it expects to make.

The Committee, no doubt, is fully advised as to the requirements of the "Federal Valuation Act", which became a law after the Committee was appointed. This Act specifically sets forth the principles and methods which shall govern the valuation of the railroads of the United States. Therefore, there is no longer need of speculation as to such principles and methods, so far as railroads are concerned. This "Federal Valuation Act" does not even suggest that the results to be obtained under its specifications are to be used for rate-making. The "Federal Valuation Act" calls for (1) "The Original Cost to Date"; (2) "The Cost of Reproduction New"; (3) "The Cost of Reproduction Less Depreciation"; and (4) "Other Values and Elements of Value". Consequently, any theory of valuation to be applied to railroad property must consider, not only the physical elements, but also such "other values and elements of value" as affect either the physical elements or the total value. Neither the Federal Government nor any of the several States has attempted to make valuations of railroad property for the purposes of rate-making. The carriers, in some instances, have found it necessary to produce evidence of the investment in the physical elements of their respective properties, in order to defend them from the enforcement of rates which they deemed would be confiscatory.

Public utilities, other than railroads, generally sell only one commodity or service, the price of which—especially in the case of gas, electric, and water utilities—is controlled by ordinance or the sovereign power of the State. Such public utilities are local, exist by the grace of special franchise, and are generally monopolistic. As contrasted with these public utilities, it is well known that railroads sell a great variety of service in competition, and are under regulation by the Interstate Commerce Commission. In the case of a railroad, there is a very great variety of rates, involving, in whole or in part, identical

stretches of the property. In the speaker's opinion, therefore, it is unreasonable to suggest that there can be a determination of each of the thousands of different rates which obtain on a carrier's property by attempting to fix the value of the physical elements of the whole property. Mr. Hansel.

It is submitted that the report is based on a fundamental error, *viz.*, that railroad rates are based on the valuation of the property of the railroad company. It will be seen, from an examination of decisions of the Interstate Commerce Commission, of the Courts, and from leading textbooks on the subject, that the rates of a railroad company are based on:

(*a*) Value of service;
(*b*) Commercial and competitive conditions;
(*c*) And in some slight degree, though very remotely, on the cost of service.

The first railroads in the United States were merely temporary paths to greatness. Modern methods of construction were not applied in the original building of any of these earlier railroads. They were built along the line of least resistance, without regard to grade or curvature. The policy of the original constructors was to build as cheaply as possible. To cheapness of construction was sacrificed shortness of line and flatness of grade and curvature. This policy, perhaps, was the better one at the time it was adopted, because the country was sparsely settled, and the most sanguine failed to grasp the growth that was to follow.

The problem with the railroads to-day is not so much how to get more business as how to carry the existing traffic at low cost. The economic demands of modern traffic require, on the part of such railroads as the Pennsylvania, the Baltimore and Ohio, the Vanderbilt Lines, the Harriman Lines, and others, that they expend enormous sums of money on improvements which are, in a large measure, merely corrective of original defects in location and construction resulting from former methods and from enforced economy due to the high price of money and the uncertainty of earnings.

The cost of operation per train-mile is approximately the same whether the train has a capacity of 200 or of 400 tons. It is evident, therefore, that—given the same rate and tonnage—the earning capacity of a railroad which, by reason of its flat grade and easy curvature, can haul 400 tons per train on a given tonnage would be much greater than the earnings of another railroad which, with the same equipment, could haul only 200 tons; and it is usually found that the railroad capable of carrying the greater train load, with a given power, costs much less to build than one of smaller train capacity. As the contractional relations between railroads influence the tonnage very mate-

Mr. Hansel.

rially, it is quite possible that the cheaper railroad, having the greater train-load capacity, would be short of business on account of not being as favorably situated to receive tonnage from other roads.

There are cases where it would be economical, from a broad public policy, for a railroad to abandon its line entirely and build in different territory between two given cities, thereby saving in operating cost for carrying the same tonnage between the same termini. In many cases this saving of cost of operation capitalized would more than equal the cost of building a new line. This change cannot always be accomplished, for the reason that towns and industries must be served. Consequently, the high cost of carriage between the termini must continue; and, if a new organization constructed a line in the easier territory suggested, and secured satisfactory terminals and traffic arrangements, it is apparent that it could conduct its business at a smaller cost and with greater expedition. The securing of business, however, depends not only on convenient terminals and efficient organizations, but also on the contractional relations with other railroads which are in a position to give or withhold business; and, though the value of the physical elements of the least costly railroad, as represented by the real estate and the tangible personal property, may be much less than that of its competitors, the commercial value may be much greater by reason of its maximum train-load capacity and its minimum operating expense.

The value of low gradients and the following conditions actually exist in one of the Southern States:

"A" represents the train load of a Cooper E-50 on a grade of 15.84 ft. to the mile, or 0.3 of 1%; load, 3 022 tons.

"B" represents the train load on a grade of 53 ft. to the mile, or 1%; load, 1 322 tons.

"C" represents the train load on a grade of 60 ft. to the mile; 1.136%; load, 1 191 tons.

It is understood that the speed of the train is 18 miles per hour, the tractive force is 0.2 of the weight on the drivers, and the train resistance on the level is 6.5 lb. per ton.

It is evident that, if these three railroads have an equal division of business, and like rates, between two important cities which they connect, the net earnings of "A" will greatly exceed those of either "B" or "C". However, it is not likely that the division of business is equal, and before a final determination of value is made, the actual tonnage hauled should be ascertained; and this current tonnage is frequently controlled through contractional relations with other roads, which may vary from time to time.

If the property investment or physical value of the parts constituting the three railroad properties cited were used to determine the

justice of rates, line "A" would be given a rate about one-half of that of line "C". Mr. Hansel.

Referring to page 6 of the report: The statement that "valuation is for the purpose of determining rates which shall be a limitation of charges to those which shall give a fair return" is entirely erroneous. It has been held by the Interstate Commerce Commission and by the Courts that rates which gave more than a fair return, might be entirely reasonable; and so, also, it has been held that a given rate which affords less than a reasonable return might still be a reasonably maximum rate. The only case in which the question of return as affecting rates is of the slightest importance is where a Governmental body proceeds to establish an entire schedule of rates, and where the carrier contends that the schedule as established affords less than a reasonable return on the value of its property devoted to the public use; in other words, asserts confiscation, and accordingly a violation of its constitutional rights. If the principle be asserted that is apparently contended for in this portion of the report, that rates must be limited to such as will secure a bare return on the value of the property, it is obvious that no private capital will go into a business where the profits are limited, and where there is no guaranty against loss.

In further argument that the title is a misnomer, and that there can be no valuation for the purpose of rate-making, attention is directed to the address* of Mr. Charles A. Prouty, Interstate Commerce Commissioner, delivered at the Annual Meeting in the Chamber of Commerce of the United States, at Washington, D. C., on February 11th, 1914. Mr. Prouty is now the Director of the work involved in the valuation of railroads under the "Federal Valuation Act", consequently, his words on this subject should be carefully considered.

The principles which govern the determination of the public-service value of railroads are, in many respects, quite different from those which apply to the public-service value of other public utilities.

It will probably not be denied that railroads are the most important factor of our internal material progress. They have been constructed in advance of all other commercial developments; and, indeed, in many cases, the constructors, the bankers, and the engineers were the pioneers —the explorers of the land, at present busy with industry which now requires for its refined conveniences those other public utilities such as water, gas, and electric plants, urban and interurban transportation, and the like. Thus, the railroads stand as a necessity to the material progress of the whole country, whereas the other public utilities are local, and are created out of the demands of a refined community dependent for its being on the facilities furnished by the railroads.

The railroads differ from other public utilities in construction and maintenance. The track of a railroad is made up of small units, which

*_Railway Age Gazette_, February 13th, 1914.

Mr. Hansel.

can be currently renewed; and thus the track may be, and is, generally, kept at 100% efficiency, sufficiency, and adequacy. There is, in track and roadbed, no decrepitude or obsolescence beyond the reach of maintenance.

Stated in another way, the roadbed of the carrier, which is generally a large item of cost, is constantly appreciating through consolidation, enrichment, and growth of vegetation on slopes, thus protecting it from erosion and thereby reducing the maintenance. The track itself is constantly being renewed.

A pipe line is constantly depreciating; it is beyond the reach of maintenance; when it fails, through decrepitude or insufficiency, the investment in constructing the trench, laying the pipe line, etc., is lost; and there is practically little scrap value.

Each item of track has a different life, and the history of each is represented by a series of independent, recurring cycles, which together make up the whole and produce an approximately uniform average, which, measured by efficiency, is 100 per cent.

The "Valuation Act" requires us to apply depreciation to cost to reproduce. Therefore, we must determine a method of fixing depreciation as contemplated by the Act, though we are not apprised of the purpose to which such depreciated condition is to be applied. In making this deduction for depreciation of individual items, we do not acknowledge that by so doing we depreciate the property as an instrument of commerce, which, when maintained as in the case of the majority of the carriers, furnishes a constantly adequate and sufficient system for public service.

The Special Committee was appointed under a resolution offered in January, 1911. Since then the valuation of railroads and other public utilities has been discussed by engineers, economists, and various technical societies, also before the House and Senate Committees of Congress; and, on March 1st, 1913, there was enacted a law: that an act entitled "An Act to Regulate Commerce", approved February 4th, 1887, as amended, be further amended by adding a new section, to be known as Section 19a.

Notwithstanding the enactment of the Federal Valuation Law, no mention has been made of it in the report, although it says, on page 6:

"It is obvious that a valuation before a Court or public service commission must, in order to be sustained, be made in conformity with existing laws and the decisions of the higher Courts".

The speaker desires to direct attention to other criticisms of the report, which may be stated briefly as follows:

(1) Page 7: The third paragraph, referring to the allowance sufficient to provide for depreciation, is insufficient, in that it does not provide for an adequate surplus to serve as a basis of credit.

Mr. Hansel.

(2) Page 11: The second paragraph on this page, which apparently eliminates the amount of investment as a factor in valuation, is most unjust, as it excludes entirely from consideration cost to date, and seems to assume that all investment which has become obsolete should be written off and no return allowed thereon.

(3) Page 11: The third paragraph, which recites that rates should be limited by a valuation, is absolutely impracticable in the case of a railroad company, for the reasons heretofore set forth.

(4) Page 32: There does not seem to be any justification in equity or in law for the theory apparently set out here, that the present value must exclude that part of the investment which has been replaced by amounts charged to operating expenses.

(5) Page 50: Criticism 4 applies also to the statement in the sixth paragraph of this page, with respect to appreciation and depreciation balancing each other. The statement also is apparently in conflict with the decision of the Court in the Minnesota Rate Cost, and the Consolidated Gas Case (212 U. S.); and apparently in conflict with the last paragraph on page 60 of the report.

(6) Page 67: The statement in the second paragraph, that value resulting from increased stability of embankments and slopes cannot be taken into consideration, would seem to be legally and equitably unjustifiable.

(7) Page 70: The statement in the fourth paragraph of this page is defective, in that it does not include any provision for a surplus as a basis of credit or for unforeseen expenses due to unusual destruction by the elements.

(8) Page 73: The recommendation on this page, as to treating appreciation, would seem to be neither good law nor equity. The report apparently concedes that it is not good law.

The Interstate Commerce Commission, together with its Engineering Board, Legal Advisers, and Accountants, has been engaged since June, 1913, in formulating specifications, rules, and methods of procedure for the guidance of all concerned in the valuation of the railroad properties of the United States. Up to the present time, its efforts have been directed toward the solution of engineering problems, thus illustrating the importance and difficulty of gathering engineering data. Although Commissioner Prouty, in his address before mentioned, sets forth clearly the various problems associated with the application of depreciation and "other values and elements of value", the Commission has refrained from dealing with the complex economic questions to which the Special Committee has devoted its report.

Mr. Hansel.

Any attitude, of the Federal or State Governments, toward railroads or other public utilities, which tends to throttle progress is admittedly against sound public policy. As has been stated, it is necessary for the carriers of to-day to expend large sums of money in betterments, in order to reduce the cost of transportation in the face of advancing costs for labor, materials, and supplies.

Large expenditures have been made in the reduction of gradients for the purpose of increasing the trainload and reducing the operating cost. If the beneficial results of such expenditures are to be denied the carriers, does not such action throttle progress?

The reduction of gradients frequently involves a change in gradients on the same alignment and the moving of material at maximum cost. After the accomplishment of such work, the reproduction cost of that portion of the property affected by the betterment does not represent the cost under the actual conditions of construction; and, even though it did accurately represent the cost, it seems unwise to take from the carrier the results of his efforts to increase the safe and economical operation of the property.

It must be apparent, therefore, that any attempt to fix rates of carriage by measuring the investment in the physical property is against sound public policy, even if it were possible to carry out any such plan.

Is it then good public policy to say to the carriers that it is useless for them to attempt improvements which will provide safer and more efficient transportation? Will the carriers be able to finance additions and betterments, which frequently require the abandonment of property, if they are to be denied a reasonably attractive return on the new capital as well as on the property sacrificed to the cost of progress?

It is a matter of common knowledge, that recently a carrier, which for years has enjoyed the most efficient management, has been required, by the bankers, to agree to put aside from its net surplus such sums of money each year as will produce one-half of the amount necessary to provide additions and betterments by the time the total loan is due. This plan is wise financing from the bankers' viewpoint, but it demonstrates the needs of a carrier which arise in spite of the fact that it has so remodeled its property as to put it into the first rank as to average train loading. The money which produced the present high operating efficiency must now temporarily be denied a return, because sufficient rates of carriage have not been allowed the carrier.

Shall the Society, as an engineering body, attempt to formulate principles and methods of accounting which can apply only to the future? Is it to be expected that the problems involved in the valuation of public utilities will be solved by adopting any of the several theories advanced in the Committee's report?

As understood by the speaker, none of these theories deals with facts, but rather with assumptions of conditions which do not now exist, and

Mr. Hansel.

can never be made to exist. All the value of all property cannot be completely measured with but one template in order to determine a proper return on capital. The term "value" is the *ignis fatuus* of the law; and, though it is defined more or less clearly in some few particular statutes of some States, it is generally left untrammeled, and free to wed with "reasonable", and, thus joined, comfort the Courts and economists, who, armed with these two indefinitive terms, are no longer in need of precise language.

The conclusions of this Society on subjects relating to engineering are generally held in high regard, and though the opinions of many of its members, on subjects relating to law, ecomomics, accounting, and the like, are respected by many, it seems unwise, at this time, in view of the Federal legislation and Court decisions which have been uttered since the appointment of this Special Committee, for the Society to go on record as acknowledging and sustaining any formulation of principles and methods for the valuation of railroads or other public utilities for the purpose of rate-making.

Mr. Lum.

D. W. Lum, M. Am. Soc. C. E. (by letter).—The Special Committee's report indicates a vast amount of labor and thought, and is very interesting as representing the personal views of the members of the Committee. The various features of the subject as treated, however, do not appear to harmonize with the practical requirements, making it necessary for the reader to choose between theory and fact in reaching a conclusion as to how to proceed in the great work that is before the country at this time.

The instructions of the Society to the Committee indicated that there was to be prepared a report to formulate principles and methods for the valuation of railroad property and other public utilities; the requirement being practically in line with that which later appeared in the provisions of the Federal Act.

As the Act was passed some months before the submission of the Committee's report, it would seem that the recommendations should conform to the requirements of the Law in order to be of practical service; and as great differences appear which cannot be reconciled, one must assume that there is error.

The writer notes with regret that the report, in its first lines, makes a most important deviation from the Act, as well as departure from the order assigning the duties of the Committee, in that it has assumed a physical inventory as the important measure of a rate-making value.

It appears proper to call attention to the fact that no reference to rate-making or earning allowance was made in the Act, nor in the order creating the Committee, and to limit the consideration in this way would defeat the object of the investigation. This view is practically expressed in the following statement by the Committee (page 67):

Mr. Lum.

"There are several reasons why a physical valuation, taken by itself, furnishes an unsatisfactory basis for determining rates, and other reasons why it does not seem equitable to omit other considerations".

If, therefore, this paragraph represents a concrete expression of the Committee's views, in order that the discussion may adhere to the practical duty assigned, it would appear necessary for the report to be revised by eliminating all reference to rates and substituting principles and methods for the valuation of railroad properties and other public utilities, as described in the Act, and as called for by the Society.

The proposed untried theory of allowed sinking funds and prescribed earnings assumes so many conditions which are in direct conflict with the facts developed in the operation of a property, that one is constrained to call attention to the very familiar example as a practical demonstration of the fundamental error in the report.

Two railroads, approximately parallel, and of substantially equal length, are competing: One, reporting in accord with the suggestions of the report, would inventory physical property at $20 000 000, the other, by the same rules, would inventory $10 000 000—the more expensive road, having steep grades and adverse conditions, may cost twice as much to operate. The Committee's theory assumes that the expensive road would and must charge double the freight and passenger rate for the service, which, of course, would direct all the business to the cheaper road. The result would be that the expensive road would get no business, and would "go to the wall".

Question: If the shipper insists on using the road offering the lesser rate, even though the Committee's theory requires that the more expensive road must earn just so much each year, how does the Straight-Line Method, or the Equal-Annual-Payment Method, or any method contribute any amount in dollars to the value of the road that is not patronized. Is it not true that such a road must conform to the requirements of competition, and, on the other hand, may not the road costing the lesser amount have a value far beyond the cost of its physical construction?

If, therefore, it is not practically possible to make a separate physical "valuation for the purpose of rate-making", it would seem that the Committee should adhere to the requirements of the Law, and develop the methods and principles that are necessary at this time.

DISCUSSION ON CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS.*

By A. I. Stiles, Assoc. M. Am. Soc. C. E.

A. I. Stiles, Assoc. M. Am. Soc. C. E. (by letter).—The discussions of the report of this Committee, both in the *Proceedings* of the Society and in the technical press, seem to indicate a practically unanimous opinion that its figures and conclusions are far too optimistic. This view is supported by the writer's own experience. At the time that the information for this report was being collected, he was a member of an engineering organization employing about 20 men in the grade of transitman or higher, of whom two were members of the Society and reported their salaries to the Committee. These two men constituted the upper 10% of the entire force and their average salary was 204% of that of the remaining 90% of non-members. While somewhat more experienced than their fellows, it was by no means in such a proportion and it seems safe to assert that their salaries were at least 150% of what would have been attainable under similar conditions by the average engineer of equal length of practice. Mr. Stiles.

The writer heartily endorses the suggestion of Mr. Lundgren† that much valuable information might be obtained from a study of the salary lists of Government bureaus and large corporations, none of which seems to have any difficulty in obtaining plenty of qualified applicants for engineering positions at salaries much inferior to the Committee's averages. In the engineering department of one large railway, receiving hundreds of applications yearly, all college graduates without practical experience were informed that they would be required to begin as "track apprentices", at the same wages as common

* Continued from February, 1914, *Proceedings*.

† *Proceedings*, Am. Soc. C. E., for February, 1914.

Mr. Stiles.

labor. No particular effort was made to instruct such men as accepted this offer. They were assigned to section gangs apparently at random, and sometimes acquired valuable experience in picking up wrecks, relaying rail, ballasting, etc.; in other cases they spent months in sweeping stations, cutting grass, picking up scrap, and similar tasks. A large proportion quit in disgust and at least 75% of the "graduates", expressed themselves as considering their apprenticeship as time lost. On the completion of the "course", having at least qualified for gameness, they were employed as assistants on surveying parties at initial salaries of $50 per month and field expenses, rising gradually from "stake artists" to levelmen and transitmen. It was the announced policy of the department to promote those who made good at the rate of $5 per month after each half year's service, and to employ experienced men from outside sources at equivalent rates, so that, after 5 years' service, an assistant engineer would receive $100 per month. About 75% of them never got any higher, and finally resigned. Division engineers were paid from $150 to $200 per month, or perhaps more in rare instances, and about 5% of the entire engineering force received salaries in excess of this rate, after from 10 to 20 years of experience. Many young engineers take their first few jobs almost entirely regardless of remuneration, and on account of the valuable experience which they expect to acquire. It is much to be regretted that in many instances such experience fails to materialize, and they find themselves in the position of having purposelessly cheapened their own services and those of their fellow workers.

The advertisements frequently seen in the technical press in which persons claiming to be engineers of some experience make such statements as, "salary no object", "will accept anything", "desire to obtain work without resorting to pick and shovel", etc., reveal the principal reason for the low salaries paid to engineers in subordinate positions. The attitude indicated by these advertisers should be considered as highly unethical and steps should be taken by the Society to prevent its continuance. No union man out of work would endeavor to obtain new employment by agreeing to accept less than the standard wages of his trade, and an engineer of 10 years' practice who is unable to obtain a suitable position at a fair salary, should take up some other line of work for which he is better qualified, rather than lower the remuneration of the entire profession by continuing on engineering work at the wages of unskilled labor. It must be admitted that it would be a very difficult matter to effect the change of attitude necessary to reach the root of this evil, which would require that all engineers receiving $200 per month or less should be organized somewhat on union lines, a proceeding that few seem to consider practicable. As a preliminary to the definite discussion of any such plan, it is suggested that the Committee would do well to obtain some first-

hand information from the less fortunate elements of the profession by answering a number of current advertisements for positions or even by inserting advertisements of its own, obtaining detailed information from all applicants and tabulating the results. Mr. Stiles.

The remarks of Mr. McCullough* in regard to the numerous engineering employment bureaus are of such importance as to merit much greater amplification. Theoretically, such institutions fill a legitimate field in investigating the past records of engineers and in furnishing competent men to employers on short notice. It is possible that there are individuals and corporations in need of engineering services who could obtain them in no other way so satisfactorily as through these agencies, but the writer's experience leads him to believe that *bona fide* cases of this kind must be comparatively rare. A new enterprise might secure a chief engineer from such a source but he, in turn, should have little or no difficulty in obtaining his staff from among his former professional associates and their acquaintances, reinforced, if need be, in the lower grades, by men obtained through advertisements or by recommended graduates of technical schools. Nevertheless, it appears that large numbers of men are constantly employed through agencies, chiefly on account of the fact that many employing engineers appear to have little time for, or interest in, this phase of their work, and often allow it to be handled and controlled by unscrupulous subordinates. The writer is inclined to believe that a considerable majority of the engineers employed through bureaus are, in one way or another, the victims of exploitation. The establishment of the proposed employment bureau by the Society and the pledging of all members to employ only men recommended by it, as suggested by Mr. McCullough, would certainly be of incalculable benefit to a great number of engineers.

As most registration fees are now made refundable in the event that no position is secured, the profit of a bureau depends entirely on placing men. The legitimate demand for such service being relatively limited, employees of bureaus are accustomed to increase their business by invoking the personal interest of the appointing power. This interest is usually secured by paying to the person influencing the appointment approximately one-third of the fee paid by the appointee to the bureau. Many men have accepted money from their appointees in this indirect manner, who would not think of blackmailing them directly. As far as known to the writer, there is no agency which does not grant commissions of this nature in return for services rendered by "insiders". Under such conditions, there is little prospect of efficiency in an engineering organization, every transaction being made with an eye to the fees obtainable rather than to the interests of either employer or employees. Each separation from the service means the creation

* *Proceedings*, Am. Soc. C. E., for February, 1914.

Mr. Stiles.

of a new vacancy; each appointment is the opportunity for another fee; every competent man employed tends to block future operations; every man of ordinary incompetency is an asset, as there is always valid reason for his discharge; and all promotion or other fair treatment of employees becomes false doctrine. The writer has never known any organization where these influences were in full control, but he has become acquainted with several where they were very potent.

In the case of one large company doing business in South America, considerable difficulty was encountered in getting a sufficient number of engineers experienced in tropical work, and, consequently, the salaries offered were relatively high. Yet applicants for positions who addressed themselves to the chief engineer's office were answered by form letter about as follows:

"We are in receipt of your application for a position with this company and will probably need an engineer of your qualifications in the near future. We have a contract with the ——— Engineering Agency for supplying us with all the men we may need and if you will make application through them there is little doubt that you will shortly secure the position you desire."

Application to this agency consisted chiefly in signing an agreement to pay a fee averaging about 30% of the first month's salary.

A chief draftsman in charge of about 30 men made a regular practice of replacing at least three every month at a personal profit of about $30. No matter how poor a draftsman might be, he was never discharged until he had entirely paid his fee, and, should he give satisfaction, he might remain almost a year, but was never promoted, higher positions being filled by new men paying larger fees. On the other hand, no applicant in person ever got a position but was referred to the ——— Bureau, which was thought to know of work elsewhere.

On a large construction job in the United States, about ten inspectors were employed through agencies, and averaged about 6 months' tenure of office. The contractors were doing very poor work, apparently in collusion with the higher officials of the company. If an inspector was honest and insisted on work approximately up to specifications, he was promptly discharged for some triviality. If he was guilty of accepting poor work, it was not discovered for some months and then the contractor was paid in full for such work and the chief saved his responsibility by immediately discharging the man found to have been incompetent and employing another, thus earning another fee.

The writer believes that the general condition of the Engineering Profession can be improved only by the gradual attainment of the following:

(1) Elimination of the great number of incompetents who now constitute such a large proportion of the lower grades;

(2) Standardization of the salaries of engineers, beginning with the subordinate positions and going as high as possible; Mr. Stiles.

(3) Prevention of the exploitation of engineers by the establishment of an employment bureau by the Society, to replace present private organizations in this field.

If the engineers in the higher grades will assist their juniors in this manner, they will find that in so doing they have bettered their own condition.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE DEPRECIATION OF PUBLIC UTILITY PROPERTIES AS AFFECTING THEIR VALUATION AND FAIR RETURN.

Discussion.*

By John W. Alvord, M. Am. Soc. C. E.†

Mr. Alvord.

John W. Alvord, M. Am. Soc. C. E. (by letter).—It is a matter of great interest that so many keen minds have devoted their close attention to the discussion of this paper. The subject is a rather abstruse one, but it is one that will have to be fully understood by engineers interested in appraisal work. It is, of course, impossible to review the many interesting points brought out in the discussion; only some general thoughts can be here set forth, suggested by the reasoning in certain typical discussions.

The writer is interested to note, from Mr. Burns' discussion, the fact that the California, Idaho, and Missouri Utility Commission Laws require that sinking funds shall be established. To this information may be added the fact that the Indiana Utility Law, not only requires that such funds be established, but permits the reinvestment of such funds in extensions to the property, providing, however, that the value of such extensions shall not be added to the value of the plant as a basis of fair return or purchase.

Since this paper was written, the Society's Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities, has reported, and among its findings there is one (No. 14) in favor of deducting depreciation for the purpose of establishing fair rates. Later, the Committee issued an addition to the Progress Report, in which it amplifies methods of writing off depreciation, and concludes (page 18) "that any discussion

* Continued from February, 1914, *Proceedings*.
† Author's closure.

Mr. Alvord.

of the subject which does not recognize the inter-relation between the method of providing for the depreciation and the method of valuing the property must necessarily be defective". Attention may be further directed to the fact that, since the paper was written, the Supreme Court, Appellate Division, First Department of the State of New York, in the Kings County Lighting Company *vs.* the Public Service Commission of the State of New York, First District, has upheld the Public Service Commission in its deduction of depreciation from reproduction-cost-new, reasoning out the matter in an opinion of several pages.

The writer is of the opinion, after a careful reading of the discussion and the Progress Report of the Committee on Valuation of December 1st, 1913, and its additional report, that what is needed at this time is a paper on fundamental principles of public utility valuation, and not papers dealing with details of rate-making and depreciation. The confusion of thought existing at this time appears to be caused by lack of understanding of the fundamental principles of utility valuation by a large number of engineers who are now interested in the question, and it will be hopeless to discuss details intelligently until a substantial agreement on such principles is had. As the fundamental principles of valuation work rest in the law and its interpretation by the Courts, many engineers apparently are not generally familiar with them. A brief effort will be made in this closure to clear up one or two of the more important ones which it is necessary to comprehend in order to read the discussions of this paper intelligently.

The writer would select for review, as typical, two of the discussions, one of which has apparently assented to the propositions contained in his paper, and the other of which has dissented therefrom. The first, by Mr. F. Lavis, points out (somewhat diffidently) what seems to him to be the difficulty with that class of valuers who dissent from the deduction of the depreciation from cost new.

To the writer's mind, Mr. Lavis strikes at the root of the matter. The difficulty clearly lies in the fact that the objectors do not take note of the fact that the appreciations of plants and property are included by the reproduction method, and must be considered in connection with the depreciations, and that, if the objectors would exclude depreciation, they must logically exclude the appreciation that the reproduction method usually introduces. The same arguments which one would use to exclude depreciation can be profitably used to show that questions of appreciation should not be entertained. This is fully stated in the paper.

It is a fair guess to say that failure to recognize this fundamental principle arises because some of the engineers now studying these questions for the first time have not yet had the opportunity to serve on actual appraisals, or, if so, they have not served on both sides of

the valuation problem, which is quite as important. This appears, to the writer at least, to explain the attitude of some of the more strenuous objectors to the theory here set forth. Mr. Alvord.

No one who has been in valuation work any length of time, and has served on both sides of the controversy, can fail to notice that there are three kinds of mental attitude among valuers:

1st. There are those who approach the subject from the standpoint of the protection of the rights of property and its conservation.

2d. There are those who approach the subject from the standpoint of the rights of the public and their interest in property devoted to public use.

3d. There are those, often recruited from the other two, who are influenced by the sincere desire to find the just and equitable relation between the public interest, on the one hand, and the private interest, on the other.

Now, in these matters we are, at the present time, really studying the third type of problem; that is, the just and proper relation between the public, on the one hand, and property, on the other, and not the protection of capital alone or the public alone.

We have found in the past, and undoubtedly shall continue to find in the future, that the public, in contested cases of valuation, is extremely keen, through its counsel and engineers, to ascertain and deduct every possible item of depreciation that can be taken away from a public utility property, and, on the other hand, that investors and owners, likewise through their counsel and engineers, are fully as keen to observe every fact and element which has appreciated their property. Both these two opposing tendencies are fundamentally sound, and, as usual, the truth lies in a careful conclusion which would allow to both all reasonable depreciation and obvious appreciation. When once the principle is grasped that both depreciation and appreciation must be taken into account, much of the trouble in dealing with this depreciation problem will have vanished. The Constitution of the United States gives the owner of a public utility property the right to have it valued "as of to-day," and as a "property", with all its accretions and growth in value, much of which may not be represented by any actual cash cost; and this right goes along with the right of the public not to pay a return on the full original cost of the property if it can be shown to have lessened in value in any way. This was stated clearly in the paper, but seems to have escaped the attention of some of those who have discussed the matter.

In the case of railroad properties, for instance, the appreciation of land values must certainly be a very large item, far outweighing any loss in value through minor depreciations of rails, cars, rolling stock, and the like. In the case of electric lighting properties, on the other hand, depreciations may often largely outweigh appreciations.

Mr. Alvord.

The second discussion which the writer has selected as typical is that by Mr. Stuart K. Knox. His ideas have been set forth with great clearness and definiteness, and their amiable reasoning is so different from the unpersuasive tone adopted by Mr. Humphreys that one must be tempted, if possible, in the same spirit in which they are made, to note why one must differ from them.

Mr. Knox dissents from the writer's view on the second proposition, and introduces an interesting illustration (in amplification of the general statement in the paper), through which he seeks to show the absurdity of basing rates on depreciated property. He describes a water plant consisting solely of a pipe line, 10 miles long, costing $1 000 000, and having a life of 50 years, through which water, purchased at wholesale, is conveyed and sold at wholesale. A sinking fund of $6 550 is placed in the bank each year at 4% compound interest, which will amortize the entire line at the end of the assumed life. Mr. Knox reasons, as a first proposition, that if the sinking fund was kept intact as part of the property, the rates for service should be predicated on cost new, or, in other words, the accrued amount in the sinking fund should be permitted to earn at the same return as the rest of the property, and he concludes that this proposition, as set forth in the paper, appears to be "unassailable." The second proposition, however, he dissents from; that is, that if depreciation funds are detached or withdrawn from the property and used by the owner elsewhere in private gain, he cannot hope, as a matter of proper protection to the public, to receive rates which include a reserve fund which is not actually in hand, and so in hand that it is really part of the property. Mr. Knox proceeds to show that this proposition is not sound, by supposing that the owner of the pipe line does withdraw his sinking fund allowance and invests it elsewhere outside of the water property at the same rates of interest as it should earn as a sinking fund, and, further, supposing that the owner, in the tenth year of operation, becoming alarmed at the dwindling rates on his water transportation business, restores the fund, and christens it a "sinking fund", as part of the property.

This illustration is typical of a considerable number that have been introduced both in this discussion and in the report of the Committee on Valuation.

The difficulty of utilizing this kind of illustration is that not only is it quite unlike anything that happens in practically operated utilities, as has been set forth at length in the paper, but the further and more fundamental difficulty that it is not applicable to the problem here presented, because it is, pure and simple, the amortization of an original and actual cost. In valuation work, we are not considering the retracing of a past investment and its exact mathematical protec-

Mr. Alvord.

tion, at all, but we are considering present-day valuations made on a live and growing property in its entirety.

So far as the writer's knowledge goes, it is not customary to treat the actual past cost as something from which depreciation should be deducted. It is true that the representatives of the public often make a plea for such a procedure, but Courts, commissions, or appraisal boards, with which the writer is familiar, have not decided that depreciation should be deducted from actual past cost for the purpose of making rates unless it can be shown that past cost is present value, nor does this paper even intimate the possibility of such a proposition.

What has been attempted to set forth is that in the reproduction method—that is, cost new as of to-day—if used for determining values, should have deducted from it the depreciation before using it for the computation of rates, if an adequate fund for depreciation is not in hand. A careful re-reading of the paper will make this clear. It is true that Mr. Grunsky calls it "past investment", but the writer only quotes Mr. Grunsky's exact language to make his own distinction, that it is "property now" that is valued, more conspicuous.

Now, Mr. Knox, in all his discussion, is evidently dealing with past cost, because in one place (page 216)* he says: "Assume that the reproduction-cost-new of the pipe is $1 000 000", and in the very next paragraph he says: "In the construction of this pipe line, the owner converted $1 000 000 of money into physical plant."

"Reproduction-cost-new" with him evidently means original cost, so far as his illustration and argument is concerned at least, for that idea runs through all of his succeeding reasoning on this illustration. On page 223* he says:

"On the other hand, if we neglect the fluctuations in the prices of labor and materials, reproduction-cost-new will remain an unvarying quantity as long as no additions are made to the property."

And, further:

"The reproduction-cost-new having once been ascertained may subsequently be kept up to date merely by adding the cost of extensions as these are made, and the 'adequate' annual depreciation reserve."

The writer has been actively engaged for the past 15 years in valuation work, and has never found yet that reproduction-cost-new would remain an unvarying quantity, even in plants which were not being extended. Nor can he understand how the value of a property, having once been ascertained, can subsequently be kept up by adding the cost of the extensions, for properties usually grow in value or decrease in value with the growth or decrease of the surrounding population and the general increase or decrease in opportunity to give service, and

* *Proceedings*, Am. Soc. C. E., for January, 1914.

Mr. Alvord.

this entirely outside of and irrespective of the money actually put into them.

Mr. Knox must unquestionably realize, as any engineer would realize on second thought, that utility properties in actual life may appreciate or depreciate in value outside of their original cost, and that, if growth is found, it is conceded to be the property of the owner, by the Constitution of the United States, as interpreted by the Supreme Court in numerous cases.

Mr. Knox's discussion, therefore, has only been taken as typical of this neglect to take into account possible appreciation, but he is followed in this respect by no less than six out of the sixteen discussions. The writer will try to make this fundamental difference clear.

"Past cost" is commonly understood to indicate the actual monies originally expended for the upbuilding of a property. It is one of the elements to consider in reasoning from cost evidence to value, but the Courts generally hold that it is not a controlling element.

Past cost is seldom a good measure of value except in the case of quite recent expenditures. Past cost may have in it monies expended for obsolescent structures, but it contains none of the appreciations which commonly accrue to a property, and often accrue without actual expenditure. Because it has none of these appreciations, it is not proper to deduct from past cost the appreciations; and in actual practice it is not done unless some attempt is made to compute and add the appreciations as well.

Reproduction cost is the method of computing the cost to reproduce the "property" as of to-day, in a manner that is humanly possible, and at market prices for labor and material, and including the development of the business. Consequently, it contains many of the appreciations that have come to the property by reason of the growth of its environment. Not all of these appreciations have cost actual cash; some of them are natural accretions or earned and unearned increments, which have cost the owner nothing. From such an estimate should be taken the depreciations which the existing property has suffered by reason of its age, changing conditions, or use. After this is done, if the result, in connection with other lines of evidence, is found to be properly value, as distinguished from cost, then that value may be taken to estimate the fair return.

Now, all this is elementary, and in preparing the paper it was assumed that these fundamental principles were understood, but to guard fully against misconception at the very outset, the paper states that we are discussing only that line of evidence as to value known as the reproduction method, or cost-new-less-depreciation.

Mr. Wilgus speaks of a balance sheet showing an excess of assets over liabilities. This surely relates to past cost. Farther along he

Mr. Alvord.

speaks of an "impaired investment", showing that he has investment in mind and not reproduction-cost-new.

Mr. Willoughby says: "it is the ultimate finding of the accounting * * * that fixes the value of the utility," and though he immediately apprehends that we are limited to reproduction methods, yet he later speaks of such methods as though they were recent past cost, and in his illustration lapses into past cost completely again.

Mr. Boes clearly does not have in mind that we are discussing a "property", the value of which is fixed as of to-day.

Mr. Vensano argues entirely from past cost, and uses past cost in his illustration.

The Special Committee on Valuation of Public Utilities argues entirely from original cost, and, in its illustrations, appears to be constantly thinking about the proper protection of original cost.

Now, taking Mr. Forbes' example, and conceding his assumptions; that is, that original cost is "value" continuously through the life of the plant, the writer would promptly concede the correctness of his argument, that depreciation should not be deducted in any case for the purpose of making rates. There can be no rational dissent from such a proposition.

Practically, however, past cost is almost never present value. A thing may be worth what it cost, or it may be worth much more, or it may be worth much less; hence, past cost is very rarely accepted by the Courts as the best evidence of present value.

Even reproduction cost, less depreciation, is not always value. A plant may often be worth more or may be worth less than it would cost to reproduce it, and though some utility properties depreciate more rapidly than they appreciate, as a usual thing they appreciate much more rapidly than they depreciate, and both facts must be taken into account. In other words, original cost, plus the algebraic sum of all the changes in cost and theoretical depreciations, should equal reproduction cost, less depreciation, as of to-day, if it were humanly possible to make such an analysis correctly, but even so, we will not have arrived at value; other matters have to be considered as well.

In fixing fair rates, the Courts have said, over and over again, that it is the fair value (not cost) of the property used and useful for the public that must be taken into account.

It is interesting to note that most of the water-works engineers who have had experience in appraisal work have not misapprehended the fundamental proposition here set forth. Mr. Kiersted and Mr. Burns, particularly, have thrown a great many interesting side-lights on the main question.

To emphasize the matter further, it may not be inappropriate to revert to Mr. Humphreys' illustration of the hen (page 227* of Mr.

* *Proceedings*, Am. Soc. C. E., for January, 1914.

Mr. Alvord.

Knox's discussion). Like a good many illustrations that do not illustrate, this one is misleading, in that it is not comparable with the actual conditions as we find them, for to make the illustration comparable with ordinary utility problems we should imagine that the hen lays more eggs as time goes by than she did originally, and is at the same time growing old.

What is the value of this hen to the consumer? Clearly more than it originally was, modified by the fact that she might soon die, and whatever the philosophy of the hennery farm manager, the Courts and commissions and practical appraisers would take both facts into account in fixing the price of eggs, especially if there were only one hen.

In conclusion, the writer is of the opinion that the trend of public utility regulation in the future is going to lean more and more to the requirement, in municipal utilities at least, that funds for depreciation, renewal, and contingency shall be largely, if not entirely, kept in hand as part of the property, subject to the control and supervision of the commissions. Such funds are not necessarily idle, as has been suggested, nor are they withdrawn from useful activity, but the public is undoubtedly much better protected, and the property is stronger and the owners' credit better when such funds are within public control and supervision.

It is a significant fact that in several cases, which have come under notice of late years, where new financing of public utilities, not under commission control, has been required, that the bankers have actually insisted on a replacement fund being created, and constantly maintained to a required amount, in order to make the property more sound and the securities issued more secure.

The case of the steam railroads presents a somewhat different aspect from the ordinary municipal utility. So much of the property of the steam roads is in land, which does not usually depreciate, and the remaining property depreciates so rapidly that, as pointed out in the Third Avenue Railroad case by Mr. Floy, it may be difficult and undesirable to create a special fund for depreciation, or find any method that would be more simple than that of maintenance, pure and simple. This, however, should not preclude the deduction of depreciation from reproduction-cost-new in cases of valuation where appreciations had been duly considered.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

JAMES EDMUND CHILDS, M. Am. Soc. C. E.*

DIED JULY 16TH, 1912.

James Edmund Childs was born at Neversink, N. Y., on July 11th, 1848, and began his railway work, in April, 1865, with the Engineering Corps engaged in the location and construction of the New York and Oswego Midland Railroad, now a part of the New York, Ontario and Western Railway.

During 1869 and 1870, he was Assistant Engineer on the Chicago and Michigan Lake Shore Railroad, now a part of the Pere Marquette Line. Later in 1870 he was Resident Engineer of the Buffalo, New York and Philadelphia Railroad, now a part of the Pennsylvania System, and in the following year, 1871, Division Engineer of the Rochester and State Line Railroad, now a part of the Buffalo, Rochester and Pittsburgh Railroad.

In 1873 Mr. Childs was engaged in the relocation of a division of the Wisconsin Central Railroad, as Division Engineer, and, in 1874 and 1875, as Assistant Engineer in charge of some improvements on the New York and Harlem Railroad, now a part of the New York Central System.

In 1876, Mr. Childs returned to the Rochester and State Line Railroad as Chief Engineer and Superintendent, and five years later, in 1881, came back, as General Superintendent, to the re-organized New York and Oswego Midland, on which as a boy, sixteen years before, he had begun his railway work.

He was also Assistant General Superintendent of the New York, West Shore and Buffalo Railroad during its construction and at the time it was opened for traffic in 1883.

In February, 1886, he was made General Manager and, in September, 1904, Vice-President and Director, of the New York, Ontario and Western. Mr. Childs was in the service of this company continuously for more than thirty years, with the exception of one year, 1889, when he was offered and accepted the position of Assistant General Manager of the Lake Shore and Michigan Southern Railway properties.

In the following year, however, he returned to the service of the New York, Ontario and Western, at the earnest request of its President

* Memoir prepared from notes by William A. Haven, M. Am. Soc. C. E., by Edward Canfield, M. Am. Soc. C. E.

and Board of Directors, in order to forward and complete the Ontario, Carbondale and Scranton Railway, then under construction from the main line to the City of Scranton, through the upper anthracite coal region. Mr. Childs remained in the service of this company as General Manager until the time of his death, filling also the positions of Vice-President and Director. By his energy and devotion to its interests and his knowledge of the property and territory which it served, he did more than any one else to promote its welfare and increase its traffic. His long service with the officers and employees, and the intimate and friendly character of his relations with them, rendered his death not only a loss to the company, but a personal sorrow to his associates.

In 1882, Mr. Childs was married to Laura Grant, a daughter of the late William H. Grant, M. Am. Soc. C. E., who survives him.

Mr. Childs was elected a Member of the American Society of Civil Engineers on December 4th, 1878.

JOSEPH POTTER COTTON, M. Am. Soc. C. E.*

DIED DECEMBER 13TH, 1913.

Joseph Potter Cotton, a son of Isaac H. and Rhoda Lamont (Potter) Cotton, was born in Bowdoin, Me., on May 8th, 1837. He was descended from old New England stock. He received his education in the public schools and academies of his home district, and worked on the neighboring farms. Later, he taught in districts schools in Maine, New Jersey, and Pennsylvania.

While he was engaged in teaching at Easton, Pa., the Civil War broke out, and, in 1862, he served as Orderly Sergeant of a company of militia at that place. In 1863, he raised and took command of Company C, Forty-eighth Regiment, Pennsylvania Volunteers, which was mustered into the service of the United States.

In 1866, Captain Cotton began his engineering work as Rodman and Leveler on the survey for the Lake Superior and Lake St. Croix Railroad in Wisconsin. In September, 1867, he entered the Government service, under the late General G. K. Warren, Corps of Engineers, U. S. A., and was engaged as Assistant Engineer on surveys of various rivers and bridges in Minnesota, Mississippi, Wisconsin, and Ohio. In 1871, he went to Newport, R. I., and, under General Warren, had charge of the construction of the breakwater at Block Island. In 1872 and 1873, with the late E. S. Chesbrough, Past-

* Memoir prepared by the Secretary from information on file at the Society House.

President, Am. Soc. C. E., he made a survey of Newport, in connection with a plan for a new system of sewerage, which plan, slightly modified, was adopted and forms the basis of the present system. Captain Cotton continued in the service of the Government until 1883, being engaged on river, harbor, and fortification work. In 1882 and 1883, he served as Commissioner and Engineer on the Seekonk River Bridge, at Providence, R. I.

In 1883, he resigned to engage in the private practice of engineering. He made his home at Newport, and became actively interested in city affairs and public improvements. From 1876 to 1883, he served as a Member of the School Committee; he was also Overseer of the Poor for three years, and Street Commissioner in 1890 and 1891. He was one of the group of citizens who framed the present city charter, and, on its adoption, he became a member of the Representative Council, serving on several of its important committees. He continued as a member of the Council until his death.

Captain Cotton was also deeply interested in the social betterment of the city and its people. He was one of the founders of the Charity Organization in 1880, and from that time until his death was an active member of its Board of Reference. He assisted in establishing the Holly Tree Coffee Rooms, the Law and Order League, and the Industrial School, and was for some years a Trustee of the Newport Hospital. His greatest public service, and one in which he took the greatest interest and pride, was rendered in connection with the Newport Co-operative Society for Saving and Building, which he was largely instrumental in founding in 1888, and of which he was the first and only President. The growth, prosperity, and efficiency of this institution is owing more to him than to any other man.

On March 26th 1867, he was married to Miss Isabella Cole, who died in 1908. He is survived by two sons, Dr. Frederic J. Cotton, of Boston, Mass., and Joseph P. Cotton, Jr., of New York City.

Captain Cotton was actively engaged in work up to the very end of his long life. He died in his sleep on December 13th, 1914, without pain and without premonition of death.

A few days later, Rear-Admiral French E. Chadwick, U. S. N., retired, wrote of him:

"Our town feels that in the death of Captain Cotton it has lost a mainstay. This loss is not only in our being deprived of a wise counsellor, an upright, clear-thinking citizen working always for the good of his fellow-men, but we have lost an exemplar of character. To old men he was an example, in age, of activity in business and public life; to the younger he was a pattern, for he exemplified in very full degree what character in the large sense means."

Joseph Potter Cotton was elected a Member of the American Society of Civil Engineers on June 7th, 1876.

NED HERBERT JANVRIN, M. Am. Soc. C. E.*

DIED JULY 17TH, 1913.

Ned Herbert Janvrin was born at Somerville, Mass., on May 20th, 1871. He was the son of Hiram Gilmore and Catherine Marriott Plummer Janvrin. An ancestor was one Jean Janvrin of the Isle of Jersey, whose son, Captain John Janvrin, sailed from Lisbon, Portugal, in 1696, and settled in Portsmouth, N. H. John, a son of Captain John Janvrin, born in 1707, was graduated from Harvard College in 1728. William Janvrin, the great-great-grandfather of Ned Herbert Janvrin, married Abigail Adams, a niece of President John Adams. A maternal ancestor, Francis Plummer, emigrated from Wales, at the foot of the Snowden Mountains, in 1635, and with his wife and two sons settled on the bank of the Parker River in Newburyport. He was the first man to keep a tavern and operate a ferry in that part of Massachusetts.

Mr. Janvrin received his early education in the schools of Somerville, having been graduated from the High School in 1890. In the fall of that year he entered the Massachusetts Institute of Technology, from which he was graduated in 1894 with an S. B. degree. George F. Swain, Past-President, Am. Soc. C. E., writes of him that "he was a conscientious, faithful, and very capable student, lending his influence toward a proper standard of discipline and attainment, and he left the school with the respect and confidence of all his teachers."

Almost immediately after his graduation he entered the drafting-room of the Boston Bridge Works, serving there until May, 1895, under J. R. Worcester, M. Am. Soc. C. E., Chief Engineer, who was impressed with his brightness, quickness of comprehension, and accuracy.

From May to November, 1895, he was employed as a Traverseman with the United States Geological Survey on survey work then in progress in New York State. He then returned to the drafting-room of the Boston Bridge Works, remaining there until December, 1896. From that time until May, 1897, he was with Mr. Worcester, during which period the train-shed for the South Station, at Boston, was being designed. Mr. Janvrin did a great deal of responsible work in the way of calculating and checking, particularly in connection with the girder work of the midway floor. In this position he showed that he was developing as an all-around designer, retaining all he had learned by experience and earlier training.

From May, 1897, to July, 1899, he was employed in the Bridge and Construction Department of the Pennsylvania Steel Company, at Steel-

*Memoir prepared by Robert Ridgway, M. Am. Soc. C. E.

ton, Pa., as a Checker and as Engineer in charge of drafting on the designs of steel bridges and viaducts.

Between July, 1899, and March, 1900, Mr. Janvrin was Assistant Bridge Engineer for the Metropolitan Street Railway of Kansas City, Mo., designing several of the Company's bridges and viaducts. He then entered the service of Messrs. Waddell and Hedrick, of that place, remaining with them until August, 1900, during which time he was connected with the design and construction of the Kansas City Viaduct.

From September to December, 1900, he was again with Mr. Worcester, assisting in the design of the steelwork for the Boston Elevated Railway Company, and from January to March, 1901, he served with Norcross Brothers, Worcester, Mass., as a Draftsman on steel building construction.

In April, 1901, he went with the American Bridge Company, remaining with it until September 15th, 1905. Until August, 1901, he was a Draftsman in the Pencoyd Plant. From then until June, 1903, he was Draftsman and Assistant Engineer, respectively, in the Eastern Division drafting-room, then located at Pencoyd, Pa., and in the Eastern Division estimating-room, also at Pencoyd. From June, 1903, to the middle of September, 1905, he was employed as Assistant Engineer in the Erecting Department of the Pittsburgh Division. His work there was mainly in connection with contracts for which the Company had sublet the erection to others. Among such works may be mentioned the erection of the Louisville and Nashville Shops, at South Louisville, Ky., and the Norfolk and Western Bridge, at Portsmouth, Ohio. The notable qualities of his character, which were impressed on his superiors on this work, were his absolute honesty, his quiet, industrious habits, and his ability as a thoroughly competent field checker of detailed drawings.

From October, 1905, to April, 1906, Mr. Janvrin was with Herbert C. Keith, M. Am. Soc. C. E., Consulting Engineer, of New York City, as a designer on several heavy steel bridges for the New York, New Haven and Hartford Railroad. Here he showed a keen perception of the points involved in several special problems which were presented, and great ability in solving them.

On April 2d, 1906, he reported for duty as Assistant Engineer with the Board of Water Supply, City of New York, and remained in its service, engaged on designs and surveys for and the construction of the Catskill Water Supply System, until his death. His purpose in taking up this work was due largely to a desire to increase his knowledge in a branch of engineering different from that in which he had been so long engaged. During this period, as opportunities offered, he received several promotions in rank and pay, on the recommendations of his superiors, for efficient service. Until September, 1906, he

was assigned to the Reservoir Department, on general survey work for the Ashokan Reservoir, during which period he had charge of a stadia party on preliminary topographical surveys. He was then transferred to the Designing Division of Headquarters' Department, and in the following spring was placed in charge of the construction and testing of an experimental section of reinforced concrete pipe, 11 ft. in diameter and 210 ft. long. The experiment was made with a view of ascertaining whether this type of construction was feasible and desirable for some of the smaller siphons of the Catskill Aqueduct where the head to be provided for was not great. The pipe consisted of seven 30-ft. units, each unit differing from the others as to the mixture of concrete, the details of reinforcement, etc. Mr. Janvrin gave the details of this work his earnest and intelligent attention, and his report of it, and of the successful hydrostatic test which followed the construction, was of material assistance to the designing force and added much to the knowledge of the subject of reinforced concrete pipes. In December, 1907, he was transferred to the Northern Aqueduct Department and assigned to its Newburgh Division, in Orange and Ulster Counties, where he assisted in locating the cut and cover aqueduct on that Division of 15 miles. When the work was placed under contract, he was at first given charge of Contract No. 16, a section of aqueduct 2½ miles long, and, later, in June, 1909, of Contract No. 45, about 5 miles long. As the intensity of the work increased, Contract No. 45 was divided into two engineering sections, and on April 1st, 1910, Mr. Janvrin was given charge of the south section. A notable feature of his section was the building, in two places, of the large concrete aqueduct of 500 000 000 gal. daily capacity on a heavy foundation embankment of earth, where the surface of the ground fell below the elevation of the aqueduct invert. The larger of the two embankments was 900 ft. long, and its maximum height, from the surface of the ground to the bottom of the aqueduct structure, was about 18 ft. On the practical completion of this section, on May 1st, 1913, he was transferred to the Designing Division of Headquarters' Department, where he remained until his death. In this last period of his work, his thorough grounding in the principles of stresses and strains in structures and his complete knowledge of steel and concrete structures were of great assistance in establishing methods of design applicable to the many subsurface gate-chambers of the City Aqueduct tunnel.

While on a vacation he was stricken with spinal meningitis, from the effects of which he died at Boston, Mass., on July 17th, 1913. For nearly 20 years he had given his earnest attention to the active practice of his profession, and his death, in his forty-second year, ended a career of much promise.

A friend of Mr. Janvrin, who had known him from his boyhood, commenting on his characteristics and ideals, writes:

"The one thing that stands out is his single-mindedness. It has been my lot to know of no man whose life from beginning to end was so perfectly straightforward, whose character was more truly clear and clean, whose ideals were more high, but this singleness of mind stands out the most sharply. There was nothing complex in his make-up, and it seems to me in these days of mixed motives in the characters of the best of men oftentimes, that such perfect singleness of mind was as remarkable as it is rare. This same singleness extended to his intellectual processes. His really brilliant mind moved straight ahead always, without waywardness. In all his social relations, the same characteristic predominated. As a boy he was a generous, kindly companion and a helpful son. As a man he was upright and honorable with the world at large, staunch and loyal to his friends, unselfish and devoted toward all his family."

Another, who became associated with him in his work soon after his graduation from college, and who formed a friendship then which lasted as long as he lived, writes of him as

"A man of clean habits and high ambitions, of excellent ability, strictly honest and honorable in all his dealings, and true to his friends."

Those who knew Mr. Janvrin well recognize these traits, and will endorse the tributes to his character paid by these friends.

He was a Mason, a member of Temple Lodge 299, Kansas City, Mo., a member of the Technology Club of New York, and of the National Geographic Society. He was interested in outdoor sports and skilled in games.

He was married, on June 20th, 1907, to Miss Avis Genevieve Grimes, of Franconia, N. H., who survives him.

Mr. Janvrin was elected a Junior of the American Society of Civil Engineers, on October 5th, 1897; an Associate Member on June 5th, 1901; and a Member on April 4th, 1911.

DAVID NEILSON MELVIN, M. Am. Soc. C. E.*

DIED JANUARY 27TH, 1914.

David Neilson Melvin was born in Glasgow, Scotland, on July 21st, 1840. He was the son of David Melvin, of Paisley, Scotland, a successful card manufacturer at Oxford, England, and also a notable figure in the temperance movement in Great Britain.

* Memoir prepared by George A. Parker, Esq., Mech. Asst. to Supt., The American Linoleum Mfg. Co., Linoleumville, N. Y.

David Neilson Melvin received his early education at the Andersonian Institute in Glasgow, and, in 1855, was apprenticed to the firm of Crawhall and Campbell, Engineers, to study drafting and to work through the shops.

In 1861, on the completion of his apprenticeship, Mr. Melvin was employed as Draftsman and Mechanical Engineer by several firms in Glasgow and vicinity, particularly by Blake, Barclay and Company, for which company he designed and superintended the construction of machinery and fireproof buildings, for some of the largest sugar-refining mills in Great Britain. He also designed the machinery and buildings for sugar mills in the West Indies.

In July, 1863, he purchased an interest in a paper mill near Oxford, England, which he operated until the abolition of the British tariff on paper made the business unprofitable. In 1865, he went to Birmingham, England, as Assistant to Mr. Henry Lea, Civil Engineer, remaining in that position until April, 1867, when he came to the United States. Shortly after his arrival Mr. Melvin obtained a patent for an improved sectional safety steam boiler, and, later, for an automatic furnace door, and also for a high-pressure engine. He was also associated with Mr. T. A. Weston, the inventor of the differential chain pulley, in Buffalo, N. Y.

Later, he was employed as Engineer and Superintendent by the Rodgers Iron Manufacturing Company, of Muskegon, Mich., and A. F. Bartlett and Company, of East Saginaw, Mich., in the production of wood-working machinery and in the manufacture of steam engines. He also superintended the erection of some of the largest lumber mills in the Michigan lumber regions.

In February, 1873, The American Linoleum Manufacturing Company was organized, and Mr. Melvin was appointed its Engineer. With Mr. Frederick Walton, the inventor of linoleum, he designed and superintended the erection of the machinery and buildings of the Company's large plant at Linoleumville, on Staten Island, New York. On the completion of this work, he succeeded Mr. Walton as Superintendent.

In 1888, Mr. Melvin invented and patented the machinery for manufacturing an inlaid linoleum, and about 1900, he brought out a patent for wood inlaid. These goods are now being manufactured exclusively under his patents. He retained his position as Superintendent until his death, which occurred at Miami, Fla., on January 27th, 1914, after a lingering illness.

Mr. Melvin was one of the original members, and a Life Member, of the American Society of Mechanical Engineers. He was also a Member of the Richmond County Automobile Society.

David Neilson Melvin was elected a Member of the American Society of Civil Engineers, on July 3d, 1878.

PETER ALEXANDER PETERSON, M. Am. Soc. C. E.*

DIED NOVEMBER 21st, 1913.

Peter Alexander Peterson was born in Niagara Falls, Ont., Canada, on November 8th, 1839. In July, 1859, after a thorough education, he was articled as a pupil in Surveying to Thomas C. Keefer, Past-President, Am. Soc. C. E., who, at that time, was Chief Engineer of the Hamilton Water-Works and of the Hamilton and Port Dover Railway. For two years, Mr. Peterson was engaged on these works, with headquarters at Hamilton, and from 1861 to 1863, on a survey for a canal from Georgian Bay to Toronto, being stationed at the latter place. In July, 1863, he obtained a license as an Ontario Land Surveyor, and during the next two years was employed on various engineering works under Mr. Keefer.

In May, 1865, Mr. Peterson left Mr. Keefer's employ to engage in the private practice of engineering, and during 1865 and 1866, he had charge of the reconstruction of three large dams on the Grand River, to replace those which had been carried away by floods caused by ice jams.

In the summer of 1867 he made surveys, plans, and estimates for the Petrolia Branch of the Great Western Railway, and, in the autumn of the same year, was appointed Resident Engineer of the Northern Division of the New York and Oswego Midland Railway. In March, 1868, he was appointed Resident Engineer of the Bathurst Division of the Intercolonial Railway, in New Brunswick, which was then being constructed.

Mr. Peterson remained with the Intercolonial Railway until September, 1872, when he resigned to accept the position of Chief Engineer of the Toronto Water-Works, the construction of which, it was estimated, would cost $2 000 000, and included a filtering basin 3 000 ft. long, 10 000 ft. of conduit from basin to pumping well (4 500 ft. of which was a 36-in. flexible pipe laid across Toronto Harbor), pumping engines, reservoir, and more than 100 miles of distribution pipes.

In 1875, Mr. Peterson was appointed by the Quebec Government as Chief Engineer of the Montreal and Ottawa Section of the Quebec, Montreal, Ottawa and Occidental Railway, which, except for that portion between Terrebonne and Montreal, had been constructed between Quebec and Ottawa. The location of the unconstructed portion was under discussion and Mr. Peterson strongly urged the adoption of the direct line from a point near Berthier to Montreal *via* Bout de l'Isle, including a large bridge at the latter place. In July, 1878, however, the late Mr. Walter Shanly made a report to the Government of Quebec

* Memoir prepared by H. Irwin, Esq., Cons. Right-of-Way and Lease Agent, Canadian Pacific Railway Company, Montreal, Que., Canada.

in which he advocated the line finally adopted, namely, *via* Terrebonne, St. Vincent de Paul, and St. Martin's Junction, with two large bridges and two long, heavy grades up to and down from Mile End. Mr. Peterson's route was afterward adopted by the Canadian Northern Quebec Railway.

As an engineer, Mr. Peterson excelled in the location and building of the substructures of bridges, and as Chief Engineer of the Montreal and Ottawa Section of the Quebec, Montreal, Ottawa and Occidental Railway, he had charge of the construction of the Chaudière Bridge between Hull and Ottawa, having one span of 254 ft., one of 160 ft., ten of 150 ft., and one of 135 ft., and of several other bridges over the Rouge, North Nation, Lievres, and Gatineau Rivers.

In 1881, he was appointed Chief Engineer of the Atlantic and North West Railway Company, under the charter of which the Canadian Pacific Railway Company built the line from Mile End Station, near Montreal, to connect with the International Railway of Canada at Lennoxville. At the same time, but under another charter, this road was extended from the International Boundary, near Megantic, to Mattawamkeag, Me. While in this position, Mr. Peterson superintended the construction of the St. Lawrence Bridge at Caughnawaga, on this line, the piers of which, with the necessary lengthening, were strong enough to carry the heavy double-track steelwork which, by a strange coincidence, was completed only a month before his death. On this line were also several large steel bridges and trestles, including the bridge over the Richelieu River and high trestles at Ship Pond and Wilson Stream.

Mr. Peterson was also Chief Engineer of the Sault Ste. Marie Bridge and of the Mission River Bridge, in British Columbia, and of many other important works.

In 1890, he was appointed Chief Engineer of the Canadian Pacific Railway Company, which position he held until February, 1902, when he was obliged to resign on account of ill health. He then became the Consulting Engineer of the Company.

In August, 1903, he was appointed Chief Engineer of the Guelph and Goderich Railway then being constructed by the Canadian Pacific Railway Company, and held that position until 1908 when he was obliged to retire from active work owing to his failing health. He made his home in Montreal, Que., Canada, where he died on November 21st, 1913.

He was elected a Member of the Institution of Civil Engineers of Great Britain on December 1st, 1874. He was also a Charter Member of the Canadian Society of Civil Engineers, and served as Vice-President in 1889, 1892, and 1893, and as President in 1894.

Mr. Peterson had taken a leading part in railway construction in Canada during the latter part of the nineteenth century. He was

most conscientious in regard to the performance of his engineering work, and strict, but fair, in his dealings with others. He was very kind-hearted, and always willing to aid any of his staff, although he required from them close attention in their work and whole-hearted discharge of their duty to their employers. Being of rather nervous disposition, he was, at first, sometimes thought to be slightly abrupt in manner, but his unvarying courtesy soon removed that impression.

Peter Alexander Peterson was elected a Member of the American Society of Civil Engineers on January 5th, 1876. He served as a Director in 1892 and 1893, and as a Vice-President in 1896 and 1897.

WALLACE BERKLEY RIEGNER, M. Am. Soc. C. E.*

DIED JANUARY 19TH, 1914.

Wallace Berkley Riegner, the son of Aaron H. and Caroline S. Riegner, was born in Strawsburg, Franklin County, Pa., on January 27th, 1854. In his early boyhood his parents moved to Chambersburg, Pa., where he attended the public schools, from which, as well as from the Chambersburg Academy, he was graduated. He afterward entered Lafayette College from which he was graduated with high honors in June, 1877. While at Lafayette he received the Junior Mathematical Prize, the Senior Astronomical Prize, and was chosen to deliver the Honorary Philosophical Oration. He also represented his College in the Intercollegiate Mathematical Contest.

After his graduation, Mr. Riegner taught mechanical drawing in the public schools of Reading, Pa., for about one year. On October 27th, 1879, he entered the Engineering Department of the Schuylkill Canal where he remained until March 1st, 1880, when he went to Pottstown, Pa., as Assistant Engineer on the Philadelphia and Reading Railroad, remaining in this position until August 31st of the same year.

He then went South and from December, 1880, to December, 1881, was engaged on surveys and construction work, on the Elizabeth City and Norfolk Railroad. He afterward returned to the Engineering Department of the Schuylkill Canal, with headquarters at Reading, Pa.

In April, 1882, Mr. Riegner resigned his position with the Schuylkill Canal Company to enter the employ of the Philadelphia and Reading Railway Company. From April, 1882, to July, 1883, he was engaged as Division Engineer on the Shamokin, Sunbury and Lewisburg Division, and from July, 1883, to April, 1887, as Assistant Engineer on general field and office work and the design of railroad structures at the company's office in Philadelphia, Pa. In April, 1887, he

* Memoir prepared by William Hunter, M. Am. Soc. C. E.

was appointed Engineer of Bridges, which position he held at the time of his death which took place at Chambersburg, Pa., on January 19th, 1914.

Mr. Riegner was a Member of the American Society for Testing Materials, the Franklin Institute, and the Engineers' Club of Philadelphia.

He was an intelligent, energetic, and capable engineer, modest to a degree, with a strong grasp of details which enabled him to prosecute his work most successfully.

Mr. Riegner was elected a Member of the American Society of Civil Engineers on September 7th, 1904.

HENRY HELM CLAYTON, Jun. Am. Soc. C. E.*

DIED APRIL 8TH, 1913.

Henry Helm Clayton, the son of Lillie Sale and John Benjamin Clayton, was born in Sappington, Mo., on February 8th, 1885. He received his education at the Kirkwood Public School and the Manual Training School at St. Louis, Mo., and was graduated from the latter in January, 1903.

Mr. Clayton began work as Rodman with the Terminal Railroad Association of St. Louis, where he remained until June, 1903, when he accepted a position on the International Mexican Railroad. Having won a scholarship in the Engineering Department of Washington University, he returned to the United States in September, 1903, to enter that University, and in June, 1907, he was graduated with the degree of B. S. in Civil Engineering.

He then went to Texas as Rodman on construction work for the Rock Island Railroad, but during the same year he accepted a position as Computer for the Board of Examination and Survey of the Mississisippi River Commission. He remained in this position only a short time, returning to Texas to enter again the employ of the Rock Island Railroad Company, which position he retained until the work there was completed.

In January, 1908, Mr. Clayton formed a partnership for the private practice of engineering, with offices at Clayton and Kirkwood, Mo., which partnership was dissolved in December of the same year. In the meantime he had been appointed City Engineer of Wellston, Mo., but resigned this position to enter the service of the United Railways Company of St. Louis.

* Memoir prepared by John B. Clayton, Jr., Esq.

In May, 1909, Mr. Clayton joined the forces of the Missouri Pacific Railroad and continued in the employ of that company in various positions until his death on April 8th, 1913. In January, 1910, he was appointed Assistant Division Engineer on the Arkansas Division of the St. Louis, Iron Mountain and Southern Railroad. On June 1st, 1911, he was sent to Chester, Ill., as Assistant Division Engineer on the Illinois Division, where he remained until December 1st, 1912, when he returned to the Southern District.

Mr. Clayton was a man of irreproachable character and of strong personal magnetism, and was unusually energetic in the faithful execution of his work. Having a warm heart and a generous disposition, he was true and faithful as a friend. His make-up was that of a big man, and it is believed that he would have accomplished big things had his life been spared.

Mr. Clayton was a Thirty-second Degree Mason. He was elected a Junior of the American Society of Civil Engineers on December 3d, 1907.

SOME PRINCIPLES RELATING TO THE ADMINISTRATION OF STREAMS.

By Clarence T. Johnston, M. Am. Soc. C. E.

To be Presented September 2d, 1914.

Synopsis.

The laws generally applied in the United States in the administration of streams originated in the countries of Northern Europe. These countries developed under the feudal system, in contrast to Egypt, India, and China where, at a very early date, wise principles relating to the administration of streams were discovered and applied in practice.

Northern Italy is a striking example in so far as the development of principles relating to the administration of streams is concerned. Under the dominion of the Roman Empire, wise principles were applied. Spain brought other ideas of a beneficial character. The influence of the countries of Northern Europe, from which we borrow many of our laws and customs, was detrimental to the people of the Valley of the Po.

The doctrine of riparian rights is of feudal origin. It contains no positive principle, and it has outlived its usefulness. It can only be applied by the Courts, and the decisions of our tribunals of justice are

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

not in harmony as to the interpretations which should be given the doctrine according to character of uses and varying climatic conditions. We should not depart from a doctrine which has been followed for many years, until we have something better to suggest in its place.

The first principle that should be recognized is that of public ownership of streams, lakes, and other bodies of surface water. The recognition of this principle lays the foundation for an administration which, without great expense to the various water users, can protect all in proportion to the uses perfected, the character of such use, and with due consideration of all public interests.

Priority in time of use shall give the better right.

The right to use water gives the user no property interest in the water itself, and such right cannot be separated from the use, or transferred to other uses by such user. As long as the user has no personal control of the water supply, he has nothing with which he can speculate to the injury of others.

Preferred uses should be stated in order, in the law, and then protected in proportion to the value of each in preserving the lives of the people and promoting the general prosperity of any particular area.

Beneficial use should be the measure, the limit, and the basis of the right.

A declaration of abandonment should be made when the user fails to apply the water to some beneficial purpose within a reasonably short, specific time.

Even had these principles been recognized by the Courts, it would have been difficult for these tribunals to secure and judge the relative importance of the technical data that must be at hand before a just determination of rights may be made.

A compromise between Court and direct administrative control brings but little reform, because the responsibility is then divided and the defects of both systems are likely to be magnified.

The administration of streams lies within the field of the engineer. The best governed countries of the world, in this respect, have long since provided technical departments which administer this kind of public business in a very satisfactory way. The history of some of the countries of Europe is being repeated in America, and the engineer should be ready to accept the responsibility that, sooner or later, must come to him.

The manners and customs of the countries of Northern Europe have been introduced in the United States and accepted quite generally by the people. The climate and topography of the eastern half of the American Continent compare favorably with those of England, France, and Germany. It is natural, possibly, that the rules applied in the administration of streams, during the early history of America should be similar to the regulations enforced on the Thames, the Seine, and the Rhine. Where irrigation is essential to agriculture, we find an early interest manifested in problems relating to the diversion and use of water. The influences of the countries of Northern Europe in this particular would be more healthful if irrigation were practised there. It is probably unfortunate that the people of the United States have not been taught, by some early experience, that streams should be considered public property and one of the great natural resources.

In the older, irrigated districts of the world we find some good examples of wise laws relating to the administration of streams. China and India can teach us many lessons. The modern system adopted by Australia merits our study. Egypt, that land which has never enjoyed freedom, and has always been a victim of war, famine, and pestilence, administers its one river, the Nile, in a manner which can only call for praise from citizens of countries which boast of a higher type of civilization. Although the rulers of Egypt, both foreign and domestic, have robbed the people of their lands, have taxed them to the extreme limit, have compelled them to labor for the public without compensation, and by centuries of oppression have destroyed their initiative and broken their spirit, yet the Nile has always been public property. It is the great highway of commerce. It is the life of agriculture and the foundation of every other industry. The Nile is administered by public officers for the general benefit of the people. No private rights, which tend to threaten the prosperity of the people, are recognized or protected. The principles that have been accepted by Egypt are fundamental in their character, and they are applied uniformly throughout the extent of the Nile Valley. There is no conflict between farmers under the same canal, between communities depending on different canals, or between adjoining provinces. The principles that are essential are so simple that the native can understand and appreciate them. This immediately brings about a feeling of mutual confidence and respect between the water user and the officer in charge

of the local administration. Finally, there is no litigation in Egypt between users of water, whether they be individual farmers, corporations, or municipalities.

The laws of Imperial Rome, relating to the administration of streams, furnish examples which are superior to those we have introduced from the countries of Northern Europe. These laws were based on the idea of public ownership of streams. They recognized that water must be diverted from the natural channel of streams, in many cases, if beneficial uses are to be served and protected. They gave the builders of canals and other works the right to condemn private property. Those building improvements of this kind were obliged to respect the rights of others and to compensate those whose property was injured.

Northern Italy, like Egypt, has been a battle ground where the nations of the world have staged many important campaigns. Spain, France, and other nations have in turn dominated portions of the Valley of the Po. The influence of these invaders has been felt long after they surrendered political control. It would be assumed that the influence of Spain would not be detrimental in so far as the administration of streams was concerned. This was demonstrated. That country had gone through an experience that was profitable. The invasion of the Moors was beneficial to Spain in this respect, because these people from Northern Africa had been reared in districts where public control of the water supply was essential to life. The Spanish influence in Northern Italy, therefore, was salutary.

The influence of the people of France and Germany was detrimental. The countries of Northern Europe had developed under the feudal system. Because it was not necessary to divert large volumes of water from the streams to support the population, safe and sane principles were not evolved at home, and no apparent effort was made to discover and introduce rules that had been applied in countries which had experienced healthy, early development. The feudal countries always emphasized the importance of protecting private property for the benefit of the few owners thereof. The countries of Southern Europe and Northern Africa, on the other hand, recognized at an early date the necessity of public supervision of streams for the benefit of the many. When a portion of the Valley of the Po fell under the dominion of France, principles of feudal origin were intro-

duced. Concessions were made by the State and then by the Church. The fortunate individuals who received these concessions became owners of specific volumes of water, and speculation became general. The principles of the original Roman law were broken down here and there, and much confusion resulted. Litigation soon began, and many of these cases remained in the Courts in some form for several hundreds of years. Not until 1884 did Italy recover from this influence, in so far as its laws were concerned, and it will be many years before it recovers fully. Some plan must be formulated, and then carried into effect, whereby the old concession may be canceled. While Northern Italy was throwing off the customs it had inherited through early years of feudal association, some of our Western States were passing through a similar experience. The reforms that have taken place there and here are quite similar, yet neither country has profited by the experience of the other.

As the customs of Northern Europe, rather than those of other countries, were first introduced into the United States, we are somewhat concerned in their origin, the principles they embraced, and the method in which they were applied. As streams were of only passing importance to the feudal lords, and as private property was not held by the masses, it was probably apparent to them that a single rule might answer for all time. It was plain that some rule should be applied which would prevent the pollution of streams. As streams were of some importance to navigation, and as the owners of land bordering the watercourses desired stable conditions, in so far as discharge was concerned, it did not seem wise to encourage diversions from the rivers which would materially affect the flow thereof. The rule which gradually developed is approximately as follows: All persons owning lands abutting on a natural stream have the right to demand that the waters of that stream shall pass their lands undefiled in quality and undiminished in quantity. We call this the doctrine of riparian rights.

If this rule is carried into effect rigidly, water cannot be diverted from a stream in any way. The thirsty laborer who drinks from a convenient brook must diminish the "quantity" of water flowing therein. Streams must become more or less "defiled" with every contact with animal life. It was a theoretical rule, in the first place, this doctrine of riparian rights. As it had its birth in oppression and

despotism, so its application to the streams of our time has brought political and industrial slavery and injustice. The doctrine is a part of the unwritten law of England. Because it is theoretical in character and based on no well-defined working principles, it has furnished but little light to the Courts of our day.

The doctrine was introduced in the United States with the common law, and applied by our Courts, not by our law-makers. Its application has extended by judicial decree, so that its interpretations are only limited by the number of our Courts. It is seldom recognized and never defined by State or Federal statute. It was unjust to the Courts to thrust upon them the responsibility of protecting water users. When the law does not provide an administrative department for the purpose of transacting public business, those who would otherwise be protected must war among themselves and finally resort to tribunals of justice for relief.

We need no evidence, other than that contributed by the Courts themselves, to prove that our present methods of stream control, based on the doctrine of riparian rights, are not supported by principles that are sound. Every city, every water-power plant, every individual who resorts to the stream for domestic water supply, is violating the doctrine of riparian rights, yet this doctrine prevails almost alone east of the Missouri River. To be sure, the Courts hold that if the doctrine of riparian rights has been violated for a term of years the user may obtain a specific volume of water under what they call a prescriptive right.

Although this may give relief, in certain cases, yet it goes to demonstrate the weakness of the parent doctrine. It is an indication that the Courts recognize that some other rule must apply, if very obvious injustice is to be provided against.

The early decisions of the Supreme Court of Michigan hold that an owner of land abutting on a watercourse also owns the land of the bed of the channel to the "thread" of the stream. This term "thread" may be defined in theory, but presents some difficulties in practice. The Supreme Court of Michigan intimated, at first, that this was to be a general rule. It was to apply, and possibly has applied, to navigable streams as well as to those that are not navigable. Under this theory, the citizens of Detroit own the bed of the Detroit River to the "thread" of the stream. The same theory was stretched a little when

applied to the riparian lands bordering Lake St. Clair. It applied again to the St. Clair River, but when Lake Huron was reached the Court finally had to admit that the riparian owner had to limit his possessions at the meander survey of the lake. This would seem to show that a fundamental error had been made in the early decisions. The meander line should be considered the boundary between private and public property throughout. No private citizen can exercise exclusive control of the bed of a river without interfering with public interests. The doctrine of riparian rights, without modification, has but little to do with the protection of legitimate uses or the rights of the people at large. The Court, having no other rule to govern its acts, was compelled to construct its decisions with the timber at hand.

The writer has studied the application of the doctrine of riparian rights in countries of three continents. He has followed the history of its introduction into the United States, and watched its application as settlement has taken place, and as some kind of stream control has become necessary. He has found no two authorities who entertain the same views as to the theory of the doctrine, or as to its limitations in practice. If the doctrine has any value, if there are reasons why land owners along streams should have control of such streams, engineers, by this time, must have satisfied themselves as to the justification therefor. A discussion of the doctrine by engineers may be considered by some as an invasion of the field of the attorney. This is not true. It is not necessary to attempt to understand the intricacies of the theories that have been developed by the Courts. As the doctrine has been applied in the United States for more than 100 years, it should have demonstrated something as to its worth, and if it embraces a principle, this should be manifest to the layman. If the principles on which it is based are so obscure that they can only be understood and appreciated by the judiciary, then the doctrine should be abrogated, and something more tangible should be substituted in its place.

If the doctrine, such as it is, merits a stay of sentence, the engineer, who must always stand between the Court and the water user, should demand that its meaning be accurately and concisely defined, and its limitations be absolutely established.

The doctrine of riparian rights does intimate that the public (somewhat limited) is concerned in every stream. Court decisions, based

thereon, generally concur in the principle that the public owns the water, and only the use is acquired by private parties. The doctrine of riparian rights attaches the use to the lands owned by the riparian proprietor. A complete revolution is not necessary when we permit actual diversions of water from streams and place all rivers and their tributaries under the supervision of public officers. We simply pass from the application of a doctrine of negative principles to something positive and tangible. We may go back and study the application of the doctrine of riparian rights in other countries and satisfy ourselves as to the wisdom of affording it continued support here. When Great Britain enters new territory she does not apply the common law, to the detriment of her subjects. The doctrine of riparian rights does not apply in Egypt, South Africa, India, or Australia, as it does here. There, the Courts have never been compelled to make laws governing any resource.

Fortunately, we have some examples of better things, even in the United States. A few of our Western States have provided engineering administrations which, not only have custody of the records relating to the initiation of rights, but also determine the relative rights of all claimants. In order that such administration may do justice to private and public rights, principles are defined in the statutes that govern these departments. There, a land owner has no rights in a stream simply because his property is located along that stream. The great aim of the law is to encourage uses which develop the country, which establish homes, and, at the same time, preserve all public interests.

Before we discard a rule that has been applied for many years, we should have something better to substitute in its place. The administration of streams is very complex and difficult unless the few, wise, fundamental principles, discovered and enforced many years ago, are recognized. Though not assuming to refer to all principles that might apply, the writer will discuss a few of the more essential rules somewhat in the order of their importance. As has been intimated, the principle of public ownership of streams is the first essential to a just administration of the water supply.

a.—All streams, lakes, and other bodies of water, within the exterior boundaries of any country, should be, and always remain, public property. This means that the stream bed and the water flowing therein should be thus considered. There are many reasons why this prin-

ciple should be upheld. There is a physical reason, which is seldom considered. Streams are naturally of a public character, in so far as they are distinct from political lines. A stream, therefore, is a matter of general public concern. In addition, water cannot be privately owned. If Thothmes I had upheld the theory that private ownership of water is possible, and, to illustrate his ideas, had bottled a quantity and dedicated it to the generations of his family that followed him, the receptacle only would remain to those representing his house at the present time. Water is constantly moving. Like air, it is controlled by laws which were framed by a Higher Authority. We may enjoy the use, but not the possession.

As soon as streams, or any surface waters, become commodities for trade and speculation, the local public, responsible for such a condition, is openly defying natural laws and thereby imposing burdens on those who cannot protect themselves. No act of a despotic or careless government will work greater injury to its citizens than to permit, by decree or sanction of law, the private ownership of water. One might conceive of a government which would encourage a private monopoly of the air. It is at once apparent that this would be disastrous. Water falls in the same category, but because a profitable traffic can be carried on with apparent success, for a limited time, we are not shown, at once, the iniquity thereof. Though private parties have been able, frequently, to speculate in water, yet it is probable that the public has lost none of its inherent rights, and that both the buyer and seller have been deceived as to the real effect of the deal when consummated.

Public control of streams results in the determination of claims without great cost to water users. Where the Courts have jurisdiction, only the claimants who are financially able to maintain themselves in a controversy (that generally continues for years) can take an active part in the "adjudication" proceedings. Under the best administrative systems, the water user has no expense except that incurred in the payment of a nominal fee of two or three dollars. The public makes the surveys and measurements required, and collects all field data. The tabulation of rights is prepared by public officers, and hearings are provided where all users interested may protest against statements made as to the time water was used for beneficial purposes, and similar testimony. When the adjudication is accomplished, the final order is carried into effect by the same administration. All water users, con-

cerned in diversions from any stream and its tributaries, are brought together in the single proceeding, and no one, because of financial ability, or personal or political influence, has an advantage. High-class, public service of this kind is being performed in several of our Western States. The older administrations have had an experience of more than 20 years, and we can say now, with some assurance, that these are, in every way, a success. There, we find constitutional and statutory provisions which declare the waters of the States to be public, or the property of the State. These declarations relate to principles, and not to doctrines that have unlimited elasticity in interpretation.

b.—Priority in time of use shall give the better right. That is, the first user of the waters of a stream has a better right than any subsequent user, and the second user has a right superior to the third and those who follow, and so on. It is, perhaps, unnecessary for this principle to be discussed. It is absolutely necessary to make some such rule, particularly as between a large number of claimants concerned in a use of the same kind. It is manifest to one who gives the matter due consideration that, after the early users have made improvements and perhaps established homes, they should be protected as against later comers, who know what has taken place at the time of their appearance. This principle appeals with more force to an administrative officer, perhaps, than it does to one who has never participated in the practical work that falls to an engineer under such a system.

c.—The right to use water gives the user no property right in the water itself; such right belongs to the use and not to the user. This principle recognizes perpetual public ownership of water. The user is protected thereby, because he then belongs to a large class, all of whom are placed on the same basis, and no one person can impose on his neighbors. As long as the user has no personal control of the water supply, he has nothing with which he can speculate, to the injury of others. Although circumscribed by rigid restrictions, the legitimate user is protected, in so far as his use justifies protection, and, at the same time, he is given no special privileges.

Certain engineers framed a water law for one Western State some 20 years ago. They tried to have the measure specific in attaching the rights to use water for irrigation purposes to the land reclaimed, and to make it impossible for the owner of the land to dispose of such water right, except with the land. After some active campaigning

the bill was presented, and the framers were confident that this principle had been incorporated. They had a part in the administration of the law, and this principle was carried into effect. Within a short time an irrigator attempted to make a transfer of his water right separate from his land. Litigation began at once. This controversy in the Court was continued in an active manner for 10 or 12 years. At the end of that time the litigants had lost their farms, these having been consumed in Court costs and attorneys' fees. Finally, the Court decided that the law did not embrace the principle, and the transfer was thereby sanctioned. Those interested directly and indirectly in speculation in water joined in open hostility against any measure which had for its object the correction of the original law for the purpose of incorporating the principle therein. The friends of reform carried on a campaign for 6 years, and their efforts were finally rewarded by the enactment of adequate legislation.

To those who have observed problems of stream control from some distance, this principle may seem to be of but little importance. Wherever it has not been carried into effect extensive litigation has resulted and great injury has been done to water users who were not in a position to protect themselves. The argument made by those who oppose the principle is that any one who is damaged can secure redress in the Courts. This plan has but little to recommend it, because the weaker element is immediately eliminated from the contest. Further, the effect of a transfer, separate from the original use, is seldom apparent at the time of the transaction, and before those who are injured can appreciate the resulting damage and take steps to protect themselves, much money may have been spent in perfecting the new use. There is one exception to this general rule, however. It is often necessary to transfer rights to preferred uses. This should always be accomplished under public supervision. Should a city need water that had been formerly used for irrigation, power, or for other less important purposes, a procedure should be prescribed whereby a transfer of right to use (not a right to the water itself) may be made to the municipality in a public manner, so that all concerned may make their objections at the time, and, if injury results that cannot be foreseen, compensation can be made therefor under the direction of the administrative officers. Water cannot be maintained as public property when private parties sell water rights separate from the use to which they have been

dedicated, except under a public procedure and under the supervision and advice of public officers, so that, in carrying this last principle into effect, we are upholding another of equal importance.

d.—From the early records we are able to read it would seem that there has always smouldered in the breast of man, a feeling that all rights to use water cannot be classified in the same list. The first use that comes to mind relates to the domestic supply—water for drinking and household purposes. We must protect such uses, regardless of all other claims. It is plain that there should be preferred uses. There may be some room for debate as to the exact order in which these should be guaranteed protection. Climatic conditions, the nature of the water supply, and many other items enter as factors in such an undertaking, but an approximate estimate, which is of general application, can be made. No one will deny the necessity for protecting the individual supply for domestic purposes first. This is almost identical with municipal uses. Because many people, combined within the limits of a town, require more water than does any single claimant, the people of towns are often imposed on. Generally, under the doctrine of riparian rights, a farmer or other land owner is justified in taking water from a stream, adjoining his lands, for domestic purposes. As a rule, no effort is made to limit this use. We are compelled to suppose that it must be "reasonable". There seems to be no reason to presume that a single family, within the limits of a town, requires more water than does a farmer, living beyond its borders. Bearing in mind that the uses in both cases are equally high, and the only difference is one of local government, the question arises: When shall we deny the user within the town the same rights and privileges that are granted to the farmer? The Courts would probably justify a decision which discriminates between the two uses by the fact that the farmer is an owner of riparian lands and the city user is not. Assume that each user within the limits of the town is given a deed to a narrow strip of land connecting his property with the river bank. This will be an instance where conditions within the town may be made to fit a fine-haired theory. What, then, will be the status of the city user? He is a riparian owner in fact and a preferred user. Because he and his neighbors join together, and by combined efforts build a water system that will supply all within the limits of the city, there is no reason that we should assume that the character of the use has changed in any

way. The total demand on the stream may increase because of the growth of the town. The character of the use remains the same. Regardless of this, cities and towns have often been compelled to undergo many hardships because the Courts have generally given private enterprise the advantage wherever the two classes of claims or rights have been in conflict. As soon as a study of preferred uses is undertaken, we must begin to readjust some of our former views. If we say that the first user, as to time when use began, has the first right, should this principle apply to uses of a preferred character? When a preferred use expands and becomes a detriment to a use not preferred, what shall be done in order that the higher use may have protection and the lower use be not damaged or even confiscated? In some States, the preferred users are always protected, regardless of the effect thereof on others. This is probably a wise rule when all users understand the situation from the beginning, and when all investors know that the principle will be carried into effect. Probably the better plan is to have an understanding, with users not preferred, to the effect that as the preferred use grows, the inferior users shall relinquish certain rights and be compensated therefor at a fixed rate, regardless of the time the readjustment may take place, or the demands that may be made on the stream by the preferred user. This should all be done under public supervision. Where water is wasted during times when the supply is inadequate for all, the public should interfere. A city should be permitted to expand its use without being compelled to compensate a user who wastes water. Waste, during times of scarcity, should never occur, under any well-regulated system of public control. By waste is meant a loss of water through carelessness, or such loss as may be prevented by a reasonable expenditure of money in repairs or improvements. There are losses which cannot be prevented, and these we cannot well consider.

Where irrigation is essential to agriculture, the use of water therefore should be preferred, to a limited extent at least. Power can be developed in other ways, and power plants may be located where they will not interfere with the use of water for irrigation. The ideal relation of these uses, geographically, would require the power plants to be located up stream from the irrigation works. For instance, in a mountainous country, the greatest fall is obtained near the headwaters of the stream. This is favorable to water-power plants. If a

reservoir can be constructed on a main stream to equalize the flow of water and produce a constant head for the power plant, which then discharges into a second reservoir where the water may be stored until needed for irrigation, no interference will result. It is impossible to maintain a power plant at maximum efficiency on a reservoir where water is stored for irrigation. Irrigation demands the maximum use of water in a short period during the summer, generally speaking. The maximum demand for power often comes during the winter. The head available, at the reservoir which stores water for irrigation purposes, is at a minimum at the close of that season. The supply of water, therefore, would be irregular for the power plant, and the head would not be uniform. Some of the most disastrous litigation in foreign countries, where irrigation is a necessity, has been brought about by the establishment of power plants which retard or prevent agricultural development.

That preferred uses should be recognized and protected, all must admit. When all facts relating to uses on a single stream are brought together, the administrative officer can determine the relative rights based on other considerations; after which, giving these higher uses appropriate weight, the final adjustment can be made. It would seem difficult to balance these rights, keeping two principles in mind at the same time, but in practice this is not as troublesome as it is in theory. Preferred uses are always comparatively small, and the public generally consents whenever a public authority makes a decision which protects them.

e.—Beneficial use, and the extent thereof, at the time the determination of rights takes place, shall be the measure, the limit, and the basis of the right. Where rights and claims are in an inceptive period, the public record relating to the determination may properly mention them, and all prospective users be given a reasonable time to complete the application of water, under the plans submitted to the office of public record. These incomplete rights should be determined later, as the water is applied to beneficial purposes.

The principle of beneficial use is an important one. When it is applied, every user is restricted to a specific volume, as a maximum, and he can only use so much thereof as can be applied beneficially. Under the Court decisions of the country, generally, claimants are given specific allotments of water, and in many places they are per-

mitted to sell what they find they do not need. This practice breaks down nearly every important principle relating to stream administration. The resulting condition is almost impossible, from the standpoint of the water user. Under the principle of beneficial use, a power plant, for example, is not entitled to the uninterrupted flow of the stream, regardless of the needs of the plant. Under the doctrine of riparian rights, as it is interpreted frequently, a water-power plant can require the entire flow of a stream to reach the plant, regardless of how much thereof can be used beneficially. This permits the plant to waste as much as it pleases, and to bring damage suits, even when it is not injured by users above. If the right of the power plant is limited by the volume it can use beneficially, the owners thereof have no control of or interest in the volume that the stream furnishes in excess of the capacity of such plant.

f.—A declaration of abandonment of rights to use water must be made where water is not used for a certain specified period. The application of this principle makes it impossible for those having water rights simply to hold them without using the water. This rule is incorporated in the statutes of many Western States, yet its practical application is always hampered, because the administrative officers do not generally exercise control, and it is indeed seldom that public, rather than private, interests are upheld. We have a network of theories relating to abandonments, and though these are interesting to study within doors, they are worth but little in the field. The Courts have held almost unanimously that "to constitute abandonment there must be a concurrence of act and intent, the relinquishment of possession, and the intent not to resume it for beneficial use, so that abandonment is always voluntary, and a question of fact".* This means that a user, who has been accorded a right to apply water to some beneficial purpose, may cease all use for as long a period as he may desire, and the actual abandonment will only take place when he admits the same. This is a poor rule. When the use ceases for a limited period, this should be taken as evidence that the water right is of but little value to the former user, and he should be deprived thereof. The public is concerned in use, not in speculation. A definite period, quite brief, should be fixed by law for the interval of non-use. Where the use of

* Wiel, "Water Rights in the Western States."

water is suspended, for such a time, as a matter of convenience rather than of necessity, the right should be canceled, and those who can apply the same beneficially should be favored. The application of this principle emphasizes the principle of public control, so that it has a secondary as well as a primary value.

There are other minor principles that might be discussed. The more important general principles have been already referred to, and a law, State or National, which embodies them, will result in an equitable administration of streams. These principles are not difficult to understand. Injustice is always done when they are obscured by statutes which relate only to procedure, and Court decisions that deal with fine-haired theories. It may be said that, had these wise principles been first incorporated in the law, the Courts might have been able to "adjudicate" the various rights in a satisfactory way. The West has tested this procedure thoroughly. All such trials have resulted in failure. Reference will be made to a single Court decision, made after the doctrine of riparian rights had been abrogated. Where irrigation is practised, a large number of claimants are generally represented. Table 1 is given, without referring to any particular State or stream, yet the data are taken from the Court records. Instead of giving the names of the water users, or the ditches, the writer will simply list the adjudicated rights in order of "priority" numbers.

The adjudication was made by a judge who took pride in his ability to frame water-right decisions. If this decree was based on any principle, the latter has been carefully concealed. An examination of the table will show that there is no relation between the area irrigated and the quantity of water allotted. It would seem that the Court permitted all kinds of testimony to be given. That a large part of this was erroneous, has been demonstrated by later investigations. Surveys have shown that the areas claimed to have been irrigated are inaccurate in practically every case. In an action of this kind in the Court, the facts are often gradually concealed by a record which contains quibbles of attorneys, statements of witnesses that are valueless, rulings and motions that are to no purpose, and testimony which has no bearing on the questions to be determined. Often the record becomes so voluminous and obscure that the Court is afraid of it, and the case is indefinitely delayed.

TABLE 1.

Priority number.	Acres irrigated.	Allotment of water, in cubic feet per second.	Area, per cubic foot per second (Column 2 ÷ Column 3).
1	160	8.65	18.4
2	1 200	67.03	17.9
3	800	30.00	26.7

29	100	10.00	10.0

In another case a State made an attempt to compromise between public control of streams, through an engineering administration, and Court supervision. Under this plan, the engineering administration is to obtain the facts and the Court is to make all decisions. This compromise was not accepted by the engineers leading in the movement without protest, but it was the best that could be obtained. This law has been tried out. The facts were determined on a single stream and all its tributaries. Complete tabulations and other needed information were submitted to the Court. This basic testimony has been in the hands of the Court for some 7 years, and nothing has been done. It is not too late, fortunately, for the public to provide administrative officers to take charge of this important work. The change can take place without a revolution, except in methods. Many countries and some of our most progressive States have already taken this step. The Courts have not been offended. On the other hand, prominent jurists have assisted in the organization of such administrative systems.

Within the limits of a municipality, where public rights and public interests are always more or less apparent, we unconsciously acquiesce

in the application of many of the principles discussed in this paper. We admit that the city owns and operates the water system. This is public control of the water supply within the city limits. An individual water user cannot sell water to his neighbor. The individual cannot say that his right to use is limited only by the volume of water that may be discharged on his premises or adjoining property. Waste is not permitted where it can be controlled. The parallel might be carried farther. We find some of the principles recognized in national and international laws relating to navigation.

Laws should be framed for the purpose of carrying principles into effect. Health laws generally define principles. When an epidemic threatens a community, the laws give the health officers authority to act at once. They may interfere with the liberty and the pursuit of happiness of many people, yet we hear but little complaint. Principles are being applied, and their value is generally recognized. As a rule, experts in science, rather than in law, frame these statutes and, in a large measure, interpret them. They know what principles should govern, and the public is willing to permit these specialists to lead, provided the important, fundamental principles be upheld. In this work, the law is incidental. The principles embraced therein are of prime importance, and we seldom question any reasonable interpretation of the law. We are thankful that public health can be protected without the necessity of preliminary litigation. We are thankful that these officers can act without great danger of an injustice being served at a critical time.

Engineers, who are placed in responsible charge of streams, belong to the same category. In fact, they must co-operate with the health service and with other administrative officers. The law, to them, consists of public directions as to their duties and, above all, plain definitions of the governing principles.

The administration of streams lies essentially within the field of the engineer. The engineer understands and appreciates the physical problems that are encountered along every watercourse. He must measure the discharge of the streams and the capacity of the diversion works. He must determine the value of water-power plants and ascertain the area and value of irrigation lands. He must estimate the volumes of water that municipalities require and appreciate the relation that should exist among these various uses.

Having all field data before him, and understanding the history of governments which have solved the problems presented, he should be able to frame laws defining the principles which should apply. These laws should be brief, and the principles should be defined in such terms as to leave no doubt as to the meaning of the phrases used. The principles should be stated first, because there is no excuse for an administration until these have been selected and defined. The officers provided in the statute then have a purpose. The foundation for an organization and for just compensation has been laid. No relief has come in any country until those understanding the physical problems have led in a campaign for laws embracing essential principles. The history of the Old World is being repeated in the New. The engineer receives but little financial reward for service of this kind. It is possible that he may secure more remunerative employment under a system which gives no protection to legitimate water users. The Profession, as a body, has never avoided a plain duty because of mercenary motives. Our great engineers are loved and remembered for the service they have performed, not because of the compensation they have received.

AMERICAN SOCIETY OF CIVIL ENGINEERS

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE CONSTRUCTION OF THE KLONDIKE PIPE LINE.

By W. W. Edwards, Assoc. M. Am. Soc. C. E.

To be Presented September 2d, 1914.

Synopsis.

Recent discussion of Alaska and the determination of the Government to undertake development work there has prompted the writer to submit the following paper, as describing conditions under which one job of heavy construction in the Far North was carried out. Detailed costs, he regrets to say, were not available, but wages and conditions are described and, whenever possible, day's progress figures are given.

A detailed description of methods used in construction is given, which may serve as a guide or as a comparison for other engineers engaged in laying heavy steel pipe.

The paper describes:

(1) Conditions of climate and geography peculiar to the Far North and affecting engineering work there. In particular, the perpetually frozen ground is mentioned.

(2) Details of construction.

(3) The difficulty of getting satisfactory foundations.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

(4) Points disclosed in the test and operations of the pipe line.

The Klondike pipe line was built during 1907 and 1908 by the Yukon Gold Company, at Dawson, Yukon Territory. It is an inverted siphon crossing the Klondike River Valley, and was designed for a capacity of 125 sec-ft., which figure, however, has been slightly exceeded in operation. By reference to the profile, Fig. 1, it can be seen that the maximum head on the pipe line is about 1 100 ft. The total length of 15 760 ft. is made up of: 2 390 ft. of wood stave pipe, 49 in. inside diameter; 5 850 ft. of riveted steel pipe, 49 in. inside diameter; and 7 520 ft. of lap-welded steel pipe, 43 in. inside diameter. The steel pipe ranged in thickness from $\frac{3}{16}$ to $\frac{11}{16}$ in., and came in lengths of from 15 to 30 ft. It is the largest of several inverted siphons along the line of the Main Ditch System of the Yukon Gold Company, 70 miles in length, which supplies water for hydraulic mining operations on Bonanza Creek, near Dawson.

The location of the pipe line was determined chiefly by two conditions: It was neces-

sary to cross the valley below the junction of Bear Creek, and also to keep above the dredging ground of the Canadian Klondike Mining Company. These two determining features left little room for adjusting the line to fit the ground conditions, but it is probable that the location adopted was as good as could be obtained in any case.

As may be noted from the profile, the intake end of the pipe is on a comparatively steep side-hill. This hill is of decomposed schist covered by a foot or two of soil which supports a growth of bushes, poplars, and a few spruce trees. The flat valley of the Klondike is here about 5 000 ft. wide. It is covered with a blanket of Arctic moss from 1 to 2 ft. in depth. Below this there is a layer of frozen "muck", or vegetable mould, which is generally about 5 ft. thick, and below this is generally found gravel. This formation is peculiar to the North, and will warrant a little explanation. The frozen "muck", or "frost", as it is sometimes called, is made up of decomposed roots, moss, tree branches, etc., mixed with some little rock and sand, and the whole mass is frozen solid. The moss blanket on the surface protects it from the summer heat, and whenever this blanket is undisturbed the ground beneath the moss remains frozen the year round. If the moss covering is removed, however, allowing air and water to act on the frozen muck, it soon melts. This condition may be found in almost every river valley in the Far North, as well as on the sheltered hill slopes. In places the "frost" has been built up by the seasonal thaw not penetrating fully through the winter's freezing, and extends to a known depth of 200 ft. and unknown further depths. This condition makes the question of foundations quite serious. The "frost" is a good foundation if it is not disturbed, but, if disturbed, the structure placed in it must be frozen in and the surface mossed over again to keep out the air and water absolutely. If this cannot be done, the structure must be carried through the frozen muck to good gravel or bed-rock foundation. Frozen muck was encountered all the way across the Klondike Valley and in spots along the pipe line up the side-hill as far as the discharge box.

Only two horizontal angles were made in the pipe line, with the exception of those used in making a short offset around the base of a hill. Manholes, drains, and air-cocks were provided wherever necessary. Cast-steel expansion joints were put in every 500 ft. to allow for the expansion and contraction due to the extreme variation in tem-

perature, from 80° Fahr. in summer to —70° Fahr. in winter. One three-span steel bridge, 295 ft. long, was necessary in crossing the Klondike River, and a total of several hundred feet of pile trestle or framed trestle were put in at various places along the line. The aim was to have the pipe supported at least once in every 16 ft. Whenever the conditions warranted it, as for instance, when good foundation was deep, trestle bents were built every 32 ft. and king-post trusses were put in to give the intermediate bearing. In good material, sills were merely laid in the bottom of the pipe trench and on these the pipe was supported. Whenever the foundation was within 3 or 4 ft. of the pipe, crib supports were used; if greater than 4 ft., framed bents were used.

One anchor was put in at least every 500 ft., about midway between expansion joints, and, where necessary, they were used more frequently. Each anchor consisted of a cable wrapped around the pipe in the form of a clove hitch, the ends being made fast to two "deadmen" on opposite sides of the pipe. Each "deadman" was set in the ground about 6 ft. below the surface.

On the side-hills drains were dug at frequent intervals to lead off seepage and leakage. At every drain a bulkhead was put in which fitted closely to the pipe and effectually intercepted the water.

In many ways conditions were unique for heavy construction. Common labor was paid $4.00 per day and board, which meant a total of about $5.50 per day. The working season was short, being limited to 5 months—May 1st to October 1st. Some kinds of equipment were plentiful in the country, notably steam engines and boilers, but in other lines it was sadly lacking. A well selected stock of equipment was ordered for the job, but breakages and unforeseen difficulties sometimes caused awkward situations, in view of the distance from a base of supplies.

Power was furnished from the Yukon Gold Company's hydro-electric plant on Little Twelve Mile River, about 50 miles from the pipe line. It was delivered at the main transformer-house at 33 000 volts, and there stepped down to 2 300 volts. From there it was distributed at this voltage to the transformer banks at the several compressors and at the machine shop, where it was stepped down to 220 volts.

Construction was begun in 1907. The right of way was cleared and a small quantity of pipe trench was dug. The three-span steel

bridge over the Klondike was erected. Foundation cribs were put in the river bed, the work being done mostly while the river was frozen over and the water low. Piles were driven in the river bottom and sawed off at the gravel surface, and on them the cribs were built. These cribs were then extended to a height of about 5 ft. above high-water level and filled with rock. They were sheathed with sheet iron on the up-stream end to protect them from ice. Derricks were used in assembling the steel spans. During this season, also, a pile approach to the bridge, 400 ft. long, was built, and several other smaller pile trestles and framed trestles. Construction was halted in the midst of the working season in 1907.

In the spring of 1908 construction was begun again. It was desired to have the job completed by the following October 1st, the end of the working season. All the pipe was not then on the ground, and what was on hand was not continuous. That is, sections of pipe were missing here and there. As there were so many different kinds of pipe in the line, and as extra pieces were few, it was generally impossible to use sections of pipe interchangeably, therefore work could be started only at certain places. In the course of the work, it was necessary to start laying pipe at four different stations. An error in surveying would lead to awkward consequences where any of these headings joined, as well as at angle points in the pipe line. As there was no heavy machinery or plate for making pipe of this size in the country, and there would not be time to send "outside" for extras, it was necessary to be very careful in surveying.

All the pipe on hand was first measured up carefully and a relation established between actual measurements and those given on the blue prints. An offset line was then run paralleling the located line at a distance of 20 ft. As the seasonal thaw had loosened the original hubs so much that they could not be relied on, measurements were begun from a point on one of the bridge piers. Hubs were driven about 99 ft. apart, and measurements were taken from plumb-bob strings held from tripods. This was done on the side-hills as well as the flats. A standard pull of 15 lb. was used, the same as had been used in measuring up the pipe on hand. Corrections were made for temperature variations. Levels were run over the hubs, and horizontal distances were computed from the slope measurements and elevation differences. This system resulted in giving a first-class base line, which could be

FIG. 3.—VIEW OF INTAKE SIDE-HILL, LOOKING TOWARD DISCHARGE.

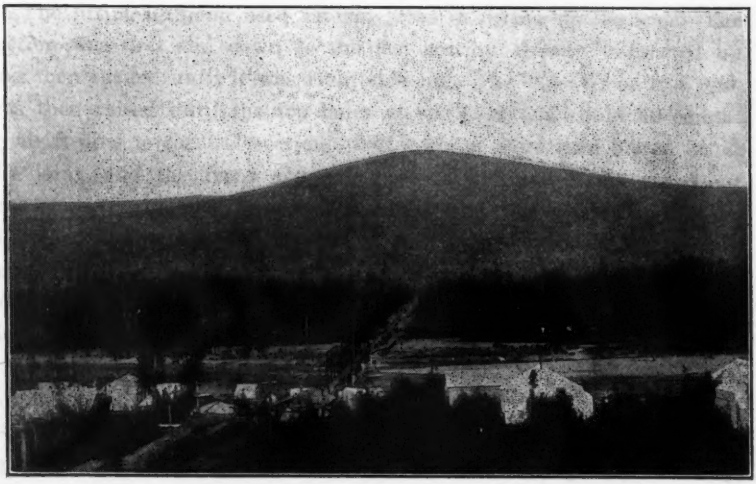

FIG. 4.—KLONDIKE RIVER AND BRIDGE, LOOKING TOWARD INTAKE.

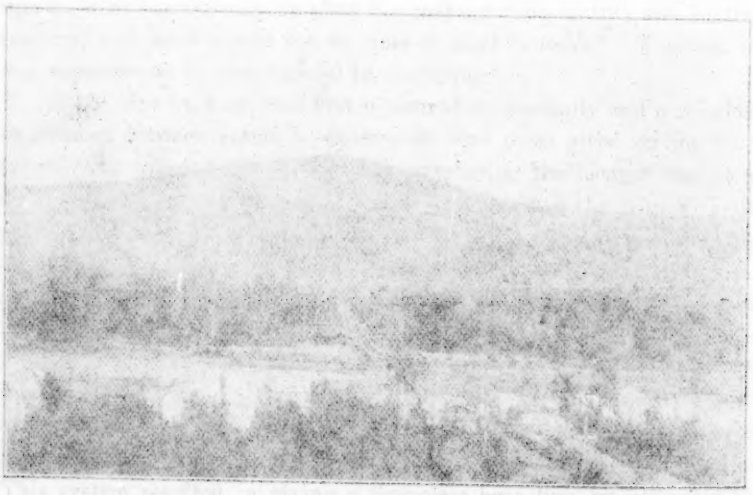

absolutely relied on in setting grades or starting points. Grades were "shot in" by transit. Points were set along the edge of the pipe trench, and were transferred to the bottom, when needed, by using a large wooden square and a carpenter's level. Bench-marks were set every 50 ft. in elevation. Levels were determined by running ahead for half a day and then tying back to the starting point.

In construction, it was frequently found advantageous to depart from the profile in order to avoid excessive excavation, and in these cases grade changes were made by shifting angle points.

Pipe was distributed along the line by a tramway. The cars were pulled by horses across the flat and by hoists on the hills. Of these hoists, two were run by steam, and one by electricity. Signals were given by use of a wire attached to a spring pole. A telephone system also helped in signaling and general communication. Turn-tables were installed on which to change the sections of pipe end for end when necessary. Steel-frame cars were used. In hoisting, a bridle was attached to the end of the pipe, and the cable was shackled to this bridle. When the pipe was at the spot desired, the cars were chained to the rail, and the pipe, with the hoisting cable still attached, was rolled into the ditch. This held the pipe from getting away on the side-hill, and the cable always had so much spring that no harm was done to the engine.

The fitting-up gang used ratchet jacks in fitting up the pipe. The section was first slid down to the last section already connected up and then turned until it was right side up. The "front", or free end, was then raised until the top holes at the back end could be caught by drift-pins to the last section. Guide-straps were then bolted on at the joint, and the front end was lowered gradually. As the front end came down, the joint was sledged and the guide-straps were tightened as necessary. When the joint was entered all around, a ratchet turnbuckle was attached and used to pull it together. Fitting-up bolts were put in every third or fourth rivet hole. Four or five sections of pipe per 10-hour shift was an average for the fitting-up gang.

Riveting, caulking, and drilling were done with pneumatic tools. Air was furnished by 8 by 8-in. Clayton air compressors run by 15-h. p., 3-phase motors. One air compressor would furnish air enough to operate a riveting hammer, caulking hammer, drills, and air dolly, with not much to spare. The compressor outfits were mounted on

platforms and moved from place to place as desired. The riveting of the holes in the bottom of the pipe was done from the inside, and of the upper holes from the outside. Air dollies were used in holding on inside the pipe and spring dollies on the outside. Each riveting gang consisted of a riveter, bucker-up, heater, and passer. An average day's work was from 160 to 180 1-in. rivets, when conditions were good. Fitting-up bolts were used liberally, and the joint was well sledged before driving each rivet. All castings were hand-riveted to the pipe, the riveting being done on the inside.

The expansion joint castings were frequently found to be too large for the pipe. In such cases the pipe was heated by a blast lamp and belled out with hammers to fit the casting. Rivet holes in all castings were drilled in the field after assembling. All caulking was done with rounded-edge fullers, the square tool being dispensed with. The riveted pipe was caulked on the outside only, the lap-welded pipe was caulked both inside and outside. Rivets were inspected with a 1-lb. tapping hammer.

The pipe was coated on the outside with a red mineral linseed oil paint and inside with a quick-drying black paraffin paint.

The wood stave pipe was of California redwood staves thoroughly seasoned. It was laid in a trench 2 ft. deep, and, when completed, was back-filled to a depth of half the diameter of the pipe, so as to give a good bearing.

The intake penstock was equipped with overflow and turn-out, as was also the discharge box. The discharge box was located on a shaded side-hill on frozen clay. This condition made necessary considerable cribbing to protect it from the sloughing of the clay when it thawed consequent on the removal of its moss covering.

Timber was secured from adjoining leases and also from river drives. It was necessary to do considerable work to protect the river banks from undercutting in the vicinity of the bridge, as they were of loose gravel, loam, and moss. Piles were driven and shear cribs put in along the river bank above the bridge. Protection cribs were also put in above the pile bents on the bridge to take the brunt of the ice pressure and to break up the ice stream.

Frozen muck, reaching to a depth of 45 ft., was encountered between Stations 84 and 90. Shafts were dug to gravel foundation and trestle bents were put in at intervals of 32 ft. Between Stations 90 and 93

a heavy cut through dredge tailings and solid rock was necessary. This was just at the base of a hill which was covered with frozen muck. The digging of this section was delayed until as late as possible so that the extreme cold would keep the overburden on the slope above from thawing on exposure, and consequent sliding.

A small spot of frozen clay was encountered at about Station 107, and the depth of good foundation being unknown, a corduroy of spruce trees was laid on the frozen clay in the bottom of the pipe trench and this was covered with about 2 ft. of gravel. A bulkhead was built around the pipe above this place to shut off all seepage and leakage, and a drain was run off to the side. The pipe was back-filled and the surface covered with moss again. Apparently, the foundation remained frozen, as no settlement was noticed.

Although work was begun at the camp about April 1st, it was not until about May 15th that all the snow was off the ground and it was possible to work to the best advantage. A night shift was put on about May 15th and continued until October 1st, by which date the pipe was all laid. The long days of the extreme northern latitude made lights unnecessary on the work until August 1st. After that, a system of arc and incandescent lights was installed, which worked very well. The missing sections of pipe began to arrive about July 1st, and from that time onward operations were rushed. A force of 350 men was used to push the work to completion. The different headings of pipe were connected up at the expansion joints. This was effected by sliding the outside ring of the expansion joint back on the pipe and then pulling it up to position after the pipe had been lined up.

A tabulation was made showing the space to be left open at the expansion joints at various temperatures, so that they would not close during the hottest or open in the coldest weather. This was followed in setting the joints. Gauges were wired on at each expansion joint so that unequal expansion or contraction could be noted and steps taken to prevent it. The coupling bolts for each expansion joint were set so that the lap in each joint could not be less than 1 in. Reference points were also put in on each 500-ft. section of pipe, so that movement could be detected. Anchors were put in at every angle point. These were generally either bulkheads of timber against the pipe, used as thrust anchors, or cables around the pipe attached to "deadmen." When possible, at the angle points, a timber crib was put completely

over the pipe and filled with rock. The high cost of transportation and the character of the foundation made concrete anchors out of the question. The only timber available was white spruce, which was soft and brittle, and had to be used with a high factor of safety in all structures.

Some trouble was experienced from the lap-welded pipe. Two makes were used on the job. One, an American make, was perfectly satisfactory, but the other, a German make, was not. One section of the second kind cracked along the weld for a distance of 10 ft. on being dropped into the pipe trench. This was patched and reinforced, and gave no trouble in operation. Another section of this pipe burst in testing under 835 ft. head. Examination showed a flaw in the metal. When it burst, the water was shot out to the side of the pipe line and little damage was done. This was the extent of the trouble with the line in testing.

In operation, the quantity of water flowing through the pipe fluctuated considerably. As the difference in elevation between intake and discharge was 195 ft., this variation caused great fluctuations in the water level in the pipe at the intake end, there being no regulating gate at the discharge end. When little water was flowing, it ran in a very rapid stream down the bottom of the wood stave pipe at the intake end. This had the result of rapidly wearing out the bottom staves, so that considerable patching had to be done.

Bulkheads were put in at each end of the pipe and all other openings were closed as soon as the pipe was thoroughly drained. Thus the air circulation inside the pipe was shut off and the subsequent snow formed a blanket which protected it from the extremes of the winter temperature. It was found that with an air temperature of — 30 or — 40° Fahr. the temperature inside the pipe was only about — 5° Fahr. In operation, the pipe is drained at the close of the working season, about October 1st, and opened again about May 1st.

The peculiar and therefore the most interesting feature of this work was, as noted before, the study of foundations and the best styles of substructures to be used in the frozen ground. In places in the North, piles of saw-dust have been placed on the moss, and buildings put on this foundation. When water is kept away, this makes a very good foundation, as the saw-dust protects the moss and the frozen ground below from heat and consequent thawing, thus insuring

stability. On this same principle, in running a road or railroad grade across frozen ground, it is best not to cut but rather to make fills on top of the moss. Thus, on a railroad grade near Nome, a fill was made of peat cut from the surface of the tundra. When dried out and packed this gave no more trouble—until it burned up—whereas a cut in frozen ground is but an invitation to perpetual trouble from slides and settlement. In flume substructures, on the Yukon Gold Company's line, on frozen side-hills, cripple bents were tried and discarded in favor of level mudsills set in the "frost", about 2 or 3 ft. below the surface at the down-hill end. These were mossed over and remained frozen unless excessive leakage thawed the ground.

Mr. A. C. Strong, of the Yukon Gold Company, developed a type of structure which suited the foundation very well. He used piles driven into holes previously thawed out by steam points. The steam point is a strong pipe, at one end of which steam is introduced. The opposite end is rounded and a small hole left through which the steam may escape. This point is started into the frozen ground and is pounded down with a hammer as fast as it thaws through the "frost" in its way. These steam points were developed and used to considerable advantage in mining the frozen gravel. In substructure work, the steam point is used until the "frost" is thawed to the desired depth. It is then removed and a pile driven into the thawed-out hole. As the surface moss is disturbed hardly at all in this process, the pile immediately freezes in and remains in this condition. At last reports, pile substructures, such as these, were giving good service. This appears to be the cheapest form of substructure as yet devised for use in ground frozen to any considerable depth.

The writer has seen but little in technical literature dealing with construction in the Far North, and hopes that some discussion may be stimulated by this paper, especially on the subject of structures founded on frozen ground.

The foregoing work was done by day labor by the Yukon Gold Company, Mr. O. B. Perry, General Manager; C. A. Thomas, M. Am. Soc. C. E., Resident Manager; H. H. Hall, Assoc. M. Am. Soc. C. E., Superintendent of Ditch Construction, and in general charge of surveys; Mr. C. G. Newton, Superintendent of Pipe Lines; and the writer, Division Engineer and General Foreman.

THE CONSTANT-ANGLE ARCH DAM.

By Lars R. Jorgensen, Assoc. M. Am. Soc. C. E.

To be Presented September 16th, 1914.

Synopsis.

There are two features which distinguish this type of dam from the ordinary arch dam. These are (1) "Economy of Material", and (2) "Ability of the Dam to act as an Arch, even Close to the Foundation, to a Much Greater Extent than the Ordinary Arch Dam." It is understood that the canyon is wider at the top than at the bottom, which is generally the case.

The first claim, "Economy of Material", is proved in the following manner. It is shown that any arch slice closing the gap between two abutments must subtend an angle of (133° theoretically) about 120° for greatest economy of material.

The constant-angle arch is designed to comply with this law as closely as possible at any elevation from crest to foundation. The length of the up-stream radius is decreased toward the foundation in the same proportion as the canyon becomes narrower, thereby keeping the angle subtended by the arch at the most economical value. In the case of an ordinary arch dam built in a V-shaped canyon, the angle subtended by the arch is rapidly getting smaller toward the lower elevations, and therefore the building material is placed in a less

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

economical position and the arch soon becomes so flat that it cannot act as an arch, but the load is carried by shear and cantilever action almost exclusively.

To prove the second claim, attention is called to the fact that the deflection of an arch when loaded is proportional to the square of the length of the up-stream radius. This radius may be several times shorter at the foundation than at the crest of the dam in the constant-angle arch design. If the radius should happen to be, say, four times shorter at the foundation than at the crest, the deflection required at the foundation would be sixteen times less than at the crest, using the same unit stresses. In such a case, the arch would be able to support sixteen times as much load at the bottom as an ordinary arch having a constant up-stream radius.

In order to obtain equal safety at all points, it is necessary that the thickness of the arch should be made the greatest in the middle, and diminish toward the abutments, especially toward the lower elevations. This is on account of the fact that an arch dam when loaded acts like a long column in compression, and such a column is weakest in the middle; besides, the central portion of the arch moves back and forth according to different load conditions, and for that reason alone the unit stresses used for this portion should be kept lower than for the more stationary portions of the dam.

It is also pointed out in the paper that the initial stresses (Poisson's ratio), due to the water pressure and to the weight of building material, can be utilized to carry a portion of the load, and that these stresses will carry the greatest proportion of the load in arch dams designed according to the constant-angle arch principle.

An approximate short-cut method for finding the proportion of the load taken by the arch and by the cantilever, respectively, is given, also some information as to the maximum foundation pressure at the toe, and the shear existing at the foundation. Finally, a few practical examples are described.

It has been the object of the writer to bring out a dam design especially adapted to high and comparatively narrow canyons. For such a condition, the constant-angle arch dam will generally show a saving of material of 33% or more over an ordinary gravity dam, and at the same time it will possess a factor of safety more than twice as great as that of the gravity dam.

This method of arch dam design shows how it is possible to make the dam take most of the load, acting as an arch, leaving only a small portion for cantilever or gravity action.

There is no single type of dam which can be readily adapted to every site, therefore a number of types have naturally been developed and applied to satisfy the different demands as these have presented themselves. This statement applies to the type of arch dam to be described in this paper, as well as to any other.

All masonry dams must be built on good rock foundation, with the exception perhaps of those of the Ambursen type, the requirements for which are not so exacting. Where the dam site is narrow and more or less V-shaped, a single arch dam of the type to be described can be built to advantage. How narrow the site must be cannot be stated in general terms, for a few calculations will have to be made to show whether there is economy in using the arch dam rather than any other type. Many dams having gravity sections have been built curved in plan, this curved form giving them considerable extra strength at the crest, especially when the arch subtends a large angle. However, the ordinary arch form gives but little extra strength at the bottom of a V-shaped canyon, because, no matter how large an angle is subtended by the arch at the crest, this angle has become small at the bottom. In other words, the arch cannot carry much load on account of its flatness. This non-action of the arch at the bottom the following method of design seeks to eliminate, besides giving a most economical distribution of material. It does not matter whether a gravity section or a much thinner one is used, the arch can be forced by the design to take up the greater portion of the load. That this is the most economical way of loading the structure should be readily admitted, as arch stress is distributed nearly evenly over the whole section, whereas the stress due to gravity action is very poorly distributed, being a maximum along the down-stream face, and diminishing to approximately zero at the up-stream face. These two stresses are in two different planes, 90° apart, thereby tending to give lateral support to each other, as both act at the same time.* This indicates

*This conclusion can be fairly well proved by the fact that when testing a cube or column of any material in compression, it swells laterally in a plane 90° from the plane of the compressive force. With lead, this is quite apparent. If this swelling be prevented, the crushing strength of the material will be materially increased.

that it is not economy to eliminate entirely the cantilever or gravity action in an arch dam, even if this were possible, as it acts like the hooping in a column, giving lateral support to the dam body. The arch action, however, must predominate, on account of the more economical distribution of stress over the section, and also in order to eliminate the large shear action otherwise introduced by the force causing the bending of the cantilever.

When an arch dam is loaded, the length of the arc is bound to become shorter, due to the deformation of the material caused by the axial stress. The only way the structure can compensate for this shortening is by deflecting down stream. If the canyon has a fairly regular shape, this deflection will be greatest at the crown of the arch and will decrease to zero at or near the abutments. This deflection of the crown introduces cantilever stresses which ordinarily reach their maximum values in the middle section, where the dam is highest and the deflection is greatest. How the load divides itself between the arch and the cantilever depends on their relative ability to carry load, and it is easily seen that if we wish to design an arch dam where the arch is to carry the greater portion of the load, we must keep the arch deflection down to a minimum, and especially at and toward the bottom, where the dam is fixed in position and cannot move. Then, too, the arch should be designed so that the amount of this deflection decreases at a uniform rate from a maximum near the crest to a minimum, as close to zero as possible, at the foundation, in which case any imaginary horizontal arch slice deflects as if it were actually independent and free to move relatively to any other slice above or below, thereby eliminating undesirable internal stresses.

In order to obtain a preliminary dam section for any given dam site the simple formula,

$$t = \frac{P R_u}{q} \qquad (1)$$

can be used for finding the thickness of a sufficient number of arch slices at different elevations. In this formula, t equals the thickness of the dam, in feet, at any given elevation; P equals the water pressure, in pounds per square foot; R_u equals the length of the up-stream radius, in feet; and q equals the average stress, in pounds per square foot, of the area of the dam section (Fig. 1).

It will now be shown how to obtain the most economical arch section, that is, a section where the material is placed so as to take up the load with minimum resulting stress. From the formula, $t = \frac{P R_u}{q}$, it is seen that the thickness, and therefore the area, of the dam section, varies in direct proportion with the radius. The volume of concrete in any arch dam is equal to the area of the section multiplied by the length of the mean arc. The length of the mean arc can be expressed as the length of the mean radius, R_m, multiplied by the subtended angle, in terms of π,

$$\text{or, } V = \text{Area} \times R_m \times 2\theta \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

where 2θ is the subtended angle.

The mean radius, R_m, equals half the width, W, of the span divided by the sine of half the subtended angle (Fig. 1). Thus

$$R_m = \frac{\frac{1}{2} W}{\text{sin. } \theta} \ldots\ldots (3)$$

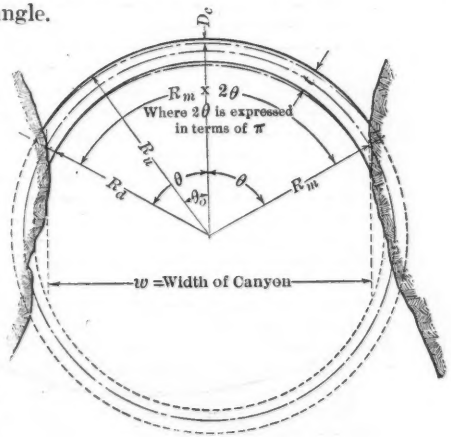

FIG. 1.

As the area of the section is proportional to the length of the radius (both to R_u and R_m), Formula 2, for the volume of masonry can be expressed thus:

$$V = C \times \frac{\left(\frac{1}{2} W\right)^2 \times 2\theta}{\text{sin.}^2 \theta} = \frac{K \times \theta}{\text{sin.}^2 \theta} \ldots\ldots\ldots\ldots (4)$$

where C and K are constants, the latter depending on the width of the canyon.

According to Formula 4, the volume varies with the term, $\frac{\theta}{\text{sin.}^2 \theta}$. The differential coefficient of this term, equated to zero, gives the minimum for a central angle of 133° 34′, which means that any horizontal slice of the dam has the least volume when $2\theta = 133° 34'$. In other words, the dam contains a minimum quantity of material when the central angle is kept at 133° 34′ at all elevations.

The curve on Fig. 2 shows this graphically; the abscissas represent the central angle, 2 θ, and the ordinates represent the term, $\frac{\theta}{\sin.^2 \theta}$, the latter being proportional to the volume of masonry. In addition to showing the point of maximum economy, this curve also shows that, as long as the subtended angle, 2 θ, is kept between the limits, 150° and 110°, the variation in the volume of masonry is very small, but that, outside these limits, the volume increases rapidly. Fig. 3 illustrates how the dimensions of successive arch-shaped slices of a dam are determined and superposed, one upon the other, to form the structure. Six elevations have been established, forming Contours

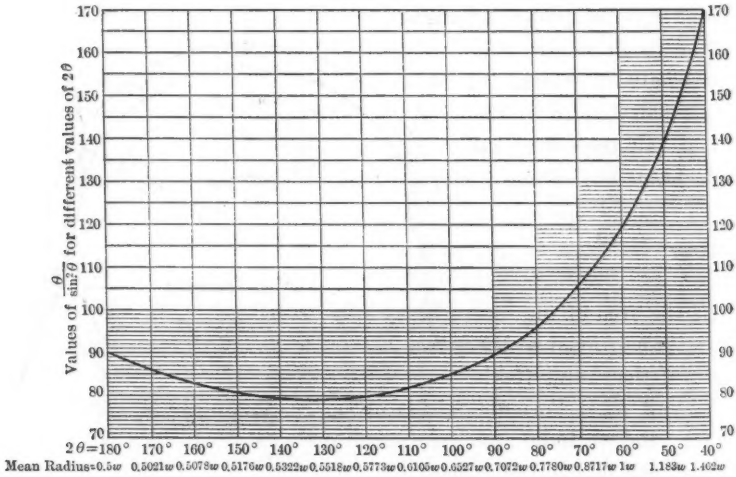

FIG. 2.

I, II, III, IV, V, and VI, Contour VI corresponding to the level of the water retained by the dam, and Contour I corresponding to the lowest water level. The distance across the canyon at the top of the dam, W_6, is measured on a map to scale. Then the mean radius, R_{m6}, which will give the dam the greatest strength with the least volume of material, is found by substituting the most economical central angle, 2 θ, in the formula $R_{m6} = \frac{\frac{1}{2} W_6}{\sin. \theta}$. The thickness, t_6 may now be determined algebraically from Equation 1. However, for the first calculation, the length of the up-stream radius will have

to be estimated from the known length of the mean radius, but this is not difficult.

At Contour V the distance, W_5, across the canyon is measured, and the most economical radius and thickness of section at this elevation is found in the same manner as for Contour VI. The center of curvature of the arch slice at Elevation V does not necessarily lie on the same center line as the center of curvature of the arch slice at Elevation VI, as perfectly symmetrical slopes of the canyon sides will rarely be found. It is desirable, however, for practical construction and appearance sake, to try and keep as many centers

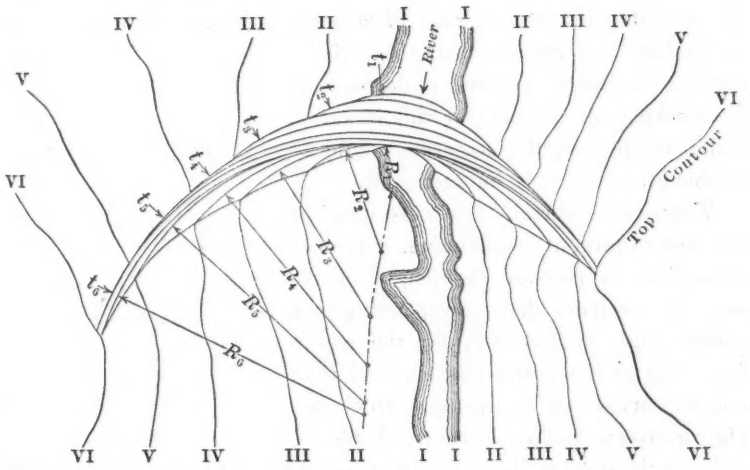

FIG. 3.

as possible on common center lines, as shown on Fig. 3. The radii and thickness at lower elevations are determined in a similar manner. It is thus seen that the main requirement which makes for high economy of material is to keep the central angle of the arch as near to the most economical value at each elevation as the contour of the site will permit. This necessitates the abandonment of the constant up-stream radius generally used in arch dams as at present constructed, and the substitution of radii of varying lengths corresponding to the widths of the canyon at different elevations. In some localities it may be desirable to face the dam with stone, and it may then be of advantage to step the faces. It will then consist of a number of

cylindrical rings superposed one upon the other. The up- and down-stream radii in such cases are ascertained in exactly the same manner as given above.

To prevent upper portions of the dam from overhanging lower portions, it will be necessary to have the thickness of the section increase from the crest toward the foundation. The proportional increase in water pressure, therefore, must be greater than the proportional decrease in length of the up-stream radius toward the foundation. The ratio of increase in water pressure is always fixed, and the ratio of decrease in the length of the up-stream radius depends on the slope of the canyon sides. If these slopes are such that at any intermediate elevation the ratio of decrease in length of the up-stream radius has been greater than the ratio of increase in water pressure, a decrease in the thickness of the dam at this elevation would result, and the structure would be overhanging, which is impracticable.

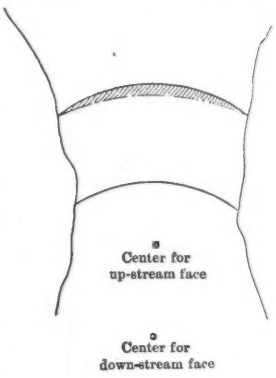

FIG. 4.

Whenever a certain thickness must be provided to prevent overhanging, it is most economical to increase the length of the mean radius above that corresponding to a central angle of 133° 24′, for the reason that a flat arch requires less material than a more curved one of the same thickness. The up-stream radius, however, should be kept small, and not have a center common with the mean radius, and of such length as to allow the deflection line (*A*, Fig. 9) to become one continuous straight line from crest to foundation. The material added is small (as shown by the cross-hatched spherical triangle in Fig. 4), as such additions are generally required only near the foundations, where the arch is short.

In the foregoing, the thickness of the different arch slices has been determined as if all the load were taken by the arch, and the dam section had no gravity action at all. How safe a dam would result depends primarily on the unit compression allowed when using Formula 1 for finding the thickness at different elevations. However, in order to obtain a dam of uniform safety for its whole height, the foregoing design must be somewhat modified to take into considera-

tion the gravity and curved beam action. The foregoing theoretical design would prove to be weakest in the middle in most cases, for the same reason that a long column held at both ends is weakest in the middle, and on account of having the highest cantilever stresses here. Whenever t is small compared with R_u, the arch when loaded is practically a long column in compression, and the length of the arch, therefore, should not be more than twenty-five times its thickness, if the material is to be highly stressed. It is true that this

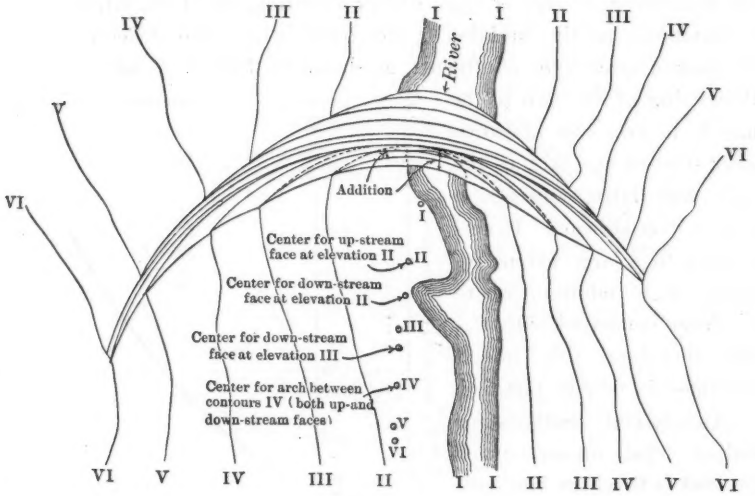

FIG. 5.

circular column is supported to some extent along one side, but this added stiffness may be largely offset by the fact that the water may not soak through the up-stream face uniformly; that is, the effect of the water pressure, in all probability, would be unsymmetrical about the center line of the dam. On a high and comparatively thin arch dam section, the resulting compression due to cantilever action and weight of material above may become excessive near the foundation, requiring some additional material along the down-stream face toward the foundation, as shown by Figs. 5 and 7. On account of the necessity for this additional material, the use of a smaller central angle than the theoretical 133° might actually be more economical, and 120° or even less, in a case like this, might give very satisfactory results (generally greater at the crest and smaller toward the foundation, depending

on local conditions). By decreasing the central angle from 133° to 120°, the volume of material is increased 1% (Fig. 2), but, at the same time, the thickness has been increased 6 per cent. For angles much smaller than 120°, the volume of additional material required increases at a greater rate than the thickness, and therefore a lower limit for the economical value of the central angle is soon reached, and extra material will then have to be added. The thickness of this added material should decrease vertically from a maximum at the foundation to zero at some higher elevation, and horizontally from a maximum in the middle, or the point where the deflection is a maximum, toward the abutments, as shown by Figs. 4, 5, and 7. This thickening of the dam in the middle to take care of cantilever stresses also stiffens the arch materially, considering it as a curved beam. It acts as such to a large extent toward the foundation, where t is large compared with R_u, and therefore this added thickness is doubly justified.

$$CC_c = \frac{\frac{2\sin.\theta}{\theta}\left(1-\cos.\theta\right)+\tfrac{1}{2}\left(\cos.2\theta-1\right)+\left(1-\cos.\theta\right)}{\frac{3\theta}{\sin.\theta}+\cos.\theta-4}$$

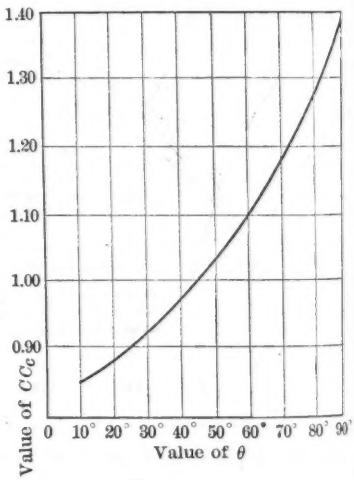

FIG. 6.

Approximate methods for finding what proportion of the load is taken by the arch and by the cantilever have been thoroughly discussed in the paper entitled "Lake Cheesman Dam and Reservoir"* by the late Charles L. Harrison, M. Am. Soc. C. E., and Silas H. Woodard, M. Am. Soc. C. E. The late R. Shirreffs, M. Am. Soc. C. E., in his discussion of that paper develops the following formula for the crown deflection of an arch dam.

$$D_c = \frac{CC_c \times P_1\ (\text{up-stream radius})^2}{E \times t} \qquad (5)$$

where $P_1 = P \times \frac{R_u}{R_m}$, and CC_c is a factor which takes the curved beam action into consideration and can be found directly from Fig. 6, which for the sake of ready reference, and on account of a typographical error in the original formula, is reproduced here from Fig. 22 in

* *Transactions*, Am. Soc. C. E., Vol. LIII, p. 89.

Mr. Shirreffs' discussion. E is the modulus of elasticity and t is the thickness. This formula and curve, however, do not take the initial stresses in the dam structure into consideration, and, therefore, before applying this formula for finding arch deflections due to the water load, we must determine how much of this load is carried by the arch due to initial stresses, because, only after deducting this part of the load does the remainder divide up between arch and cantilever action in the ordinary sense.

By initial stresses are meant stresses principally due to the weight of the structure and to the water pressure. Therefore, these stresses reach their maximum values at or near the foundation, and are zero at the crest. Thus far, they have not been much discussed, but they are very important, and should be taken into consideration when attempting to find the actual division of load between the arch and cantilever.

When the dam is completed, the lower layers of the dam body are in compression, due to the weight of the material above. When a body is compressed, the dimension in the direction of the compressive force becomes smaller, but in other directions the body swells, if free to move (lateral strain). The ratio of lateral to longitudinal strain is different for different materials. It is known to lie between $\frac{1}{3}$ and $\frac{1}{4}$ for bodies such as metals, but for concrete, which is not a very homogeneous substance, this ratio is about $\frac{1}{5}$ at the unit compression generally used in arch dam design. A. N. Talbot, M. Am. Soc. C. E., gives* values for this ratio, $\frac{1}{m}$, ranging from 0.1 to 0.18 at low loads, up to 0.25 at loads near the ultimate for 1:2:4 concrete 60 days old. A French commission on reinforced concrete found Poisson's ratio, $\frac{1}{m}$, for ordinary concrete to be about 0.16 when a force of 200 lb. per sq. in. was applied perpendicularly to the largest dimension of the concrete, and about 0.22 when applied at right angles to the largest dimension. Professor C. Bach, of Stuttgart, Germany, found for Poisson's ratio the value $\frac{1}{5.3}$ for 1:2:3 concrete 45 days old at a unit compression of about 180 lb. per sq. in.†

* *Bulletin No. 20*, University of Illinois.

† More details may be found in *Engineering News*, Vol. 68, p. 208.

A dam body often contains considerable quantities of large stones, and the presence of these stones has the effect of increasing the value of Poisson's ratio of the total mass. (Poisson's ratio for rock is about $\frac{1}{4}$.) Therefore the use of $\frac{1}{5}$ for this ratio for the total mass seems to be entirely justifiable. Any horizontal layer of material will have to sustain compression corresponding to the height of the masonry above it, and, therefore, will actually become shorter in a vertical direction and have a tendency to expand horizontally. If the abutments are unyielding, the arch may be prevented from actually becoming longer, in which case axial compression is introduced, the same as if water pressure acted on the structure. The value of this initial axial compression per square unit area is equal to the vertical compression multiplied by $\frac{1}{5}$ if the abutments are unyielding, and, as far as the final result is concerned, it does not make any difference whether they are absolutely unyielding or not.

If the specific gravity of the concrete for the dam is taken at 2.3 and the height of the dam at H, then the average vertical pressure can be expressed as $\frac{2.3\,H}{a}$, where a is the ratio of the total height of the dam to the height of a rectangular wall having the same sectional area and the same base. The ratio, a, is known as soon as the section is known, and in dam design the section must be more or less determined before final calculations can be made.

The dam section shown in Fig. 7 has an area of 9 668 sq. ft., a base width of 70 ft., and a height of 250 ft. The height of the masonry column causing the mean vertical pressure, therefore, is $\frac{9\,668}{70} = 138$ ft., and $a = \frac{250}{138} = 1.81$, making the mean vertical compression on the foundation—in terms of head of water—equal $\frac{2.3\,H}{1.81} = 1.27\,H$, with no water pressure acting on the up-stream side.

The condition of reservoir full introduces an additional force—the radial water pressure—tending to compress the dam body in a direction perpendicular to the direction of the compressive force due to the weight of the body. At the bottom of the dam this force is equal to H, in case the water is standing to the crest of the dam. In this

case the radial water pressure tends to counteract the swelling of the concrete in an up-and-down-stream direction (due to the weight), thereby introducing additional initial axial compression.

The total resulting initial axial compression at the foundation of the section shown in Fig. 7 (in terms of head of water), therefore, is

$$\frac{1}{5}(1.27\,H + H) = 0.454 \times H \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

where Poisson's ratio has been taken as $\frac{1}{5}$. Mr. H. Ballet, a French

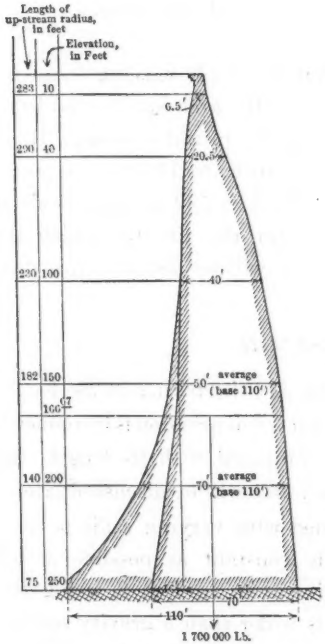

FIG. 7.

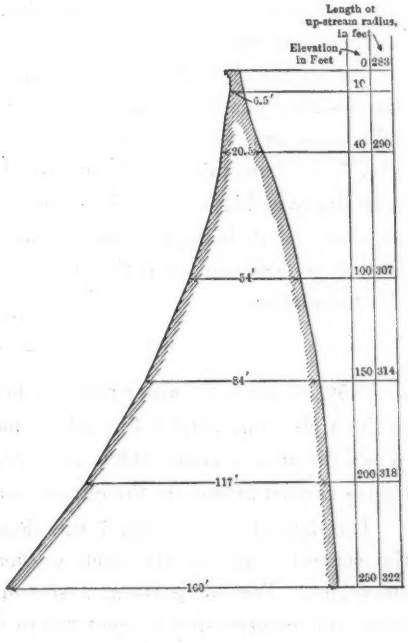

FIG. 8.

engineer, was probably the first to point out the necessity of taking Poisson's ratio into consideration when attempting to find the actual stresses in a dam body.*

The height of water, h, that this initial axial compression of 0.454 $\times$ H will resist without causing any shortening of the length of the arch at the bottom can be found by using Formula 1, thus

$$h = 0.454 \times H \frac{t}{R_u} \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXVIII, 1909, p. 51.

For the narrower section shown in Fig. 7, $t = 70$ ft. at the base, $R_u = 75$ ft. Substituting these values, it is seen that this section at the very bottom is able to carry,

$$h = 0.454 \times H \times \frac{70}{75} = 0.425 \times H,$$

or 42.5% of the total head of water, as an arch, before any shortening in the length of the arch occurs.

The initial axial compression holds in equilibrium the stresses due to 42.5% of the total head at the bottom, the remaining 57.5% of the load will divide between cantilever, arch, and curved-beam action, in the usual way.

By analyzing Formula 7 it is seen that by simply varying t and R_u, the designer has it within his power to make the arch and curved beam take more or less of the load by utilizing the initial stresses. If, in Fig. 7, the base thickness is increased from 70 ft. to 110 ft., and correspondingly at higher elevations, and R_u is kept at 75 ft., which is about as short as it is practicable to make it for the site for which the section is designed, then the initial stresses will be able to support at the foundation,

$$0.4 \times H \frac{110}{75} = 0.585 \times H,$$

or 58.5% of the total water pressure before any shortening in the length of the arch occurs, and before additional axial compression is introduced. When the arch becomes thick, however, compared with its length, the load is carried mostly on the curved beam ; this will be discussed later.

The dam shown in Fig. 7 was designed with varying radii to keep the central angle of the arch as nearly constant as possible at all elevations. For comparison, a section is shown in Fig. 8, using the same unit compression (except where it is wider than a gravity section near the foundation) and the same up-stream face batter, but a single common center for both up-stream and down-stream faces. For this section the length of the up-stream radius is also variable, but it increases toward the bottom and reaches here a value of 322 ft.

The average vertical compression on the foundation for the section shown in Fig. 8 is $\frac{2,3}{2.2} H = 1.04 \times H$, and the corresponding total initial axial compression due to the lateral deformation is

$$\frac{1}{5} (1.04 \times H + H) = 0.41 \times H.$$

The height of water which this initial stress can resist, therefore, is equal to (see Formula 7)

$$0.41 \times H \frac{160}{322} = 0.20 \times H,$$

or 20% of the total head. Comparing this with 58.5%, or 42.2% for the constant-angle arch type (Fig. 7), it is easily seen that this latter type is much more effective in utilizing the initial stresses to support the water load than the ordinary arch having its faces struck from a single center.

If a gravity section is insisted on for the arch, but the central angle is kept as nearly constant as practicable, it will be possible for the gravity section to take up the greater part of the load, acting as an arch and curved beam toward the bottom. The factor of safety has thereby been increased several times with only a slight increase in material due to the smaller average radius used in the construction of the constant-angle arch.

It may be argued that shrinkage of the concrete while setting will compensate, to a large extent, for the axial expansion. This is true when the reservoir is empty and the concrete dry, but this condition is not of nearly as much interest or importance as that of reservoir full, for which condition it is not true. In this latter case the concrete is water-soaked, and in that state the length of the arch is at least equal to the original length before setting.* It has been shown in actual practice, however, that some concrete does shrink considerably, opening up contraction joints and cracks. One way of compensating for this, is to force grout into these contraction joints, at a time when the temperature is low and the reservoir empty, after having been filled once. In this way, the permanent set of the structure will also be compensated for, and the arch and cantilever will take their respective shares of the load when the reservoir is filled the next time, and each time thereafter.

Formula 5 has been used for finding the deflection curves, A and B, of the two sections, Fig. 7 (base 110 ft.) and Fig. 8. Formula 7 has been used for correcting these curves, A and B, to take the effect of lateral strain into consideration. These curves are shown in Fig. 9, and represent the deflections of the two arches, assuming that they

* See tests reported by Messrs. A. T. Goldbeck and A. H. White at the 1911 Convention of the American Society for Testing Materials.

are free to move at the foundation. They are plotted to show how evenly the deflection curve, *A*, slants from a maximum near the top (above Elevation 40 the two arches are identical, the "horns" being two tangents 40 ft. high) to nearly nothing at the bottom in the constant-angle arch type (Fig. 7), and how little the slant curve, *B*, amounts to in the ordinary type of arch dam (Fig. 8). These curves also show very plainly that from the common arch type much arch action toward the bottom cannot be expected; cantilever and beam action must take the load, because no such deflection as 0.2624 in. could be possible at the point where the arch is fastened to the rock foundation. The constant-angle arch type for this particular site, requiring only 0.0083 in. deflection, or 31.5 times less, to support the same load, will take most of the load on itself, acting as an arch.

For dam sites where the abutments are close to one another toward the foundation, and where t is large compared with R_u, Formula 5 gives values for the crown deflection which are too large, even assuming that the dam is entirely free to move at the bottom. Though this formula considers the curved-beam action, it is at the same time understood that arch action is complete. However, where the arch is thick and the distance between the abutments is short, the arch becomes a wedge, and the horizontal curved beam takes the greater proportion of the load, because, acting in this manner, the support of the same load will require a smaller deflection.

The deflection in the middle of a beam 1 ft. wide, held at both ends, and uniformly loaded, is

$$D_b = \frac{P \times l^4}{E\,J \times 384} \qquad (5a)$$

The notations are the same as before, P being the water pressure, in pounds per square foot; l, the length of the span, in feet; E, the modulus of elasticity of concrete per square foot; and J, the moment of inertia.

Whenever Formula 5*a* gives smaller values than Formula 5, it is indicated that arch action is incomplete. The curved-beam action tends to introduce axial tension along the down-stream face in the middle, and along the up-stream face near the abutments, but the axial compression due to the partial arch action and lateral expansion (Poisson's ratio) will, or should much more than, compensate for this tendency. If it does not, the design should be changed.

$D_c = \frac{0.9 \times 12\,500 \times \frac{313}{260} \times 313^2}{432\,000\,000 \times 117} \times 12$
$D_c = \frac{0.94 \times 12\,500 \times \frac{140}{130} \times 110^2}{432\,000\,000 \times 70} \times 12$
Note :130/ft the mean length of up- and down-stream radius

FIG. 9.

From Curve *A* the deflection of the arch, Fig. 7, at the one-third point can be ascertained directly, and is found to be 0.132 in. If the cantilever, 250 ft. high and 1 ft. wide, were actually forced to deflect 0.132 in. at this point (Elevation 166.67 ft.) a force, *F*, would be required, which can be found as follows (*F* is concentrated at the one-third point):

$$D_c = \frac{8 \times F \times l^3}{E \times h^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

$$D_c = \frac{0.132}{12} = \frac{8 \times F \times 83.33^3}{432\,000\,000 \times 110^3},$$

$$F = \frac{759\,000\,000}{555} = 1\,368\,000 \text{ lb.}$$

(Where no explanation is given, formulas are taken from standard handbooks.)

The cantilever will deflect the same as the arch when thus loaded.

The total water load on a vertical slice of the dam, 1 ft. wide and 250 ft. high, is $250 \frac{0. + 15\,625}{2} = 1\,953\,125$ lb. The initial stress supports $1\,953\,125 \times \frac{16.4}{100} = 320\,312$ lb. before any deflection takes place, therefore the load causing a deflection of 0.132 in. of the combined arch and cantilever must be equal to $1\,368\,000 + 1\,953\,125 - 320\,312 = 3\,000\,813$ lb. The proportion of this amount taken by the cantilever will be $\frac{1\,368\,000}{3\,000\,813} = 45.5$ per cent.

Now, the actual load to be divided between cantilever and arch is not 3 000 813 lb. per running foot, but only $1\,953\,123 - 320\,312 = 1\,632\,813$ lb. Of this amount the cantilever carries 45.5%, or $1\,632\,813 \times \frac{45.5}{100} = 742\,930$ lb., concentrated at the one-third point, making the actual deflection at this point $0.132 \times \frac{55}{100} = 0.073$ in.

The bending moment due to this force is equal to

$$742\,930 \times 83.33 = 61\,908\,357 \text{ ft-lb.}$$

The section modulus of the base $= \frac{110^2}{6} = 2\,011$, and therefore the compressive stress on the foundation at the toe, due to the bending action of the water load on the cantilever, is equal to

$$\frac{\text{Bending moment}}{\text{Section modulus}} = \frac{61\,908\,357}{2\,011} = 30\,780 \text{ lb. per sq. ft.} \quad \ldots\ldots (9)$$

The total compression on the foundation at the toe will be this compression added to that due to the weight of the structure, which amounts to approximately 16 200 lb. per sq. ft. at the toe, making the total compression approximately 47 000 lb. per sq. ft.

If a base length of 70 ft. is chosen, the arch would take a greater percentage of the load and the curved beam a smaller, leaving the same or less for the cantilever, but, owing to the smaller section modulus of the 70-ft. base, the compression at the toe would be somewhat higher than 30 780 lb. per sq. ft., and the compression due to the weight of the structure would be much higher than 16 200 lb. per sq. ft., so that the sum of the two would be considerably more than 47 000 lb. per sq. ft. Although within the safe limit, the resulting vertical compression would be out of proportion to the 36 000 lb. per sq. ft. (and less) axial compression used when calculating t from Formula 1.

The dam section with the 110-ft. base contains only 4% more material than the dam with the 70-ft. base (Fig. 7), as the addition is not made as a portion of a circular ring, but in the shape of a spherical triangle, as indicated in Figs. 4 and 5. Any intermediate base length between the two limits given in Fig. 7 could be accepted for a dam built on this particular site. (This is shown approximately in Fig. 3, but there the tangents are not indicated.) The two stresses, the 36 000 lb. per sq. ft. average axial compression, and the maximum 47 000 lb. per sq. ft. vertical compression, are acting in planes perpendicular to each other, and therefore tend to support each other. Although they are low, the resulting section (Fig. 7) appears unusually slender on account of the economical distribution of the material.

This method of calculating the vertical stress on the foundation is correct only so long as no tension exists at the heel, or, if tension exists, so long as this tension is properly taken care of. For the constant-angle arch, where the cantilever takes the smaller proportion of the load, there will seldom be occasion for tension along the up-stream face, and there will perhaps never be enough tension to demand consideration. The accuracy of the result obtained from the use of Formula 8 depends to some extent on the face slopes, especially that of the down-stream face. The error, however, is generally such as to compensate for that made in not considering that the width of the

vertical cantilever, which is 1 ft. at the up-stream face, is less at the down-stream face. The short-cut method explained above for finding the division of the water load between cantilever and arch action and that for finding the total maximum foundation pressure, cannot be used for dams having a crown deflection curve similar to Line *B*, as this line does not show a maximum deflection near the crest and a zero deflection at the foundation. The deflection curve, *A*, answers these conditions closely enough for this purpose.

Thus far, only the middle or highest dam section has been considered, as we have been mostly interested in knowing the maximum stresses in the structure, which stresses generally occur (in high dams at least) at the toe, with reservoir full. Some modifications may be necessary near the abutments where the cantilevers, unless very short, do not support their share of the load, most of which is thrown over to the horizontal curved beam and arch, increasing the axial compression on the down-stream face from the abutments to somewhere beyond the points of contrary flexure. These points are located on both sides of the crown, and can be found from,

$$\cos.\ \theta_0 = \frac{\sin.\ \theta}{\theta} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad \ldots.(10)$$

as shown by Fig. 1. Reference should also be made to the discussion on "Lake Cheesman Dam and Reservoir".* This higher axial compression will not be entirely local, but will be transmitted from abutment to abutment through the middle of the dam, making the axial compression in the middle higher than that due to the proportionate water load carried by arch action; although still lower than the value obtained from Formula 1, assuming the whole load to be carried by the arch. The actual value may be found by drawing a graphical stress diagram, such as used for finding stresses in arch ribs for concrete bridges, etc., keeping in mind that, in the case of a dam, the directions of the forces are radial. From information as to the distribution of the axial stresses thus obtained, a new value for the deflection at the one-third point can be ascertained, and some readjustment between arch and cantilever action can be made. As long as the unit compression used is not much greater than 50 000 lb. per sq. ft., this refinement seems to be unnecessary, and hardly worth the additional labor.

* *Transactions*, Am. Soc. C. E., Vol, LIII, p. 167.

In Formula 1 only average stresses have been considered in determining the thickness of each individual arch slice. The maximum axial stresses should also be investigated. These exist along the down-stream face, and are found from the formula,

$$Q \text{ (max.)} = q \times \frac{2 R_u}{R_u + R_d} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Formula 11, however, does not give correct results toward the foundation, where the arch is thick relative to the length of the up-stream radius, and where the span is short. The proportion of the load carried by the arch in such a case is supported more by the curved-beam than by ordinary arch action. This will cause some difference in the value of Q (max.) and q (min.) (as found from Formula 11), adding to Q (max.) at and toward the abutments, and subtracting from it in the middle portion between the points of contra-flexure on the curved beam. In high dams, Q (max.) will ordinarily be lower than the vertical compression at the toe, therefore this vertical pressure is still the most important to investigate.

The influence of Poisson's ratio tends to equalize Q (max.) and q (min.) in dam sections having up-stream faces of steeper slope than their down-stream faces. In such sections the vertical pressure due to the weight of material above is greatest along the up-stream face, and therefore the initial axial compression is also greatest. It is fair to assume that this condition of relieving Q (max.) and adding to q (min.) also tends to improve the water-tightness of the dam.

In all straight gravity dams built across narrow canyons, horizontal tension exists along the down-stream face in the middle, and along the up-stream face near the abutments, at least toward the foundation. This should be very plain when it is considered that any beam fixed at both ends and uniformly loaded will support four times as much load as a cantilever of the same length sustaining the same water load (nothing at the top and a maximum at the bottom). In other words, whenever the beam is four times longer than the cantilever, it will support half of the total load, and whenever this ratio is less than four, the horizontal beam will support most of the load. The ordinary gravity design does not consider this beam action, although, when the dam is built in a fairly narrow canyon, the greatest portion of the load toward the foundation is actually carried on the

horizontal beam, and not on the cantilever. Though adding materially to the stability of the dam (as long as the horizontal tension introduced by this beam action is not greater than the breaking point, and as long as the expansion joints, if any, are placed at or near the points of contra-flexure), the foundation pressure at the toe is at the same time much relieved, a very welcome feature, especially in connection with high dams, and surely this feature should not be left out of consideration when calculating the factor of safety.

Now, if the horizontal beam is curved, horizontal axial compression takes place over the entire section, and the greater the curvature (that is, the smaller the up-stream radius) the more load will be taken by the arch, and the less remains to cause horizontal axial tension at any point of the dam faces, due to beam action. The resultant axial compression from arch action and lateral expansion will in general more than compensate for this tension. Lateral expansion due to the weight of the structure exists, of course, whether the dam is straight in plan or curved, but this alone will seldom be sufficient to compensate for the horizontal tension due to beam action in a straight gravity dam across a narrow canyon. The curvature must be introduced in order to be sure that no tension exists in this horizontal beam. For a dam 250 ft. high, the bottom width of the canyon would have to be well toward ½ mile before a gravity dam would act simply as a gravity section toward the bottom, and before the influence of the horizontal beam action would be negligible, unless it should have failed in tension first. (Near the top, the horizontal beam would have no practical influence.) It would seem logical, therefore, to provide even quite long dams with a curvature sufficient to take care of the horizontal tension. Such dams would not be true arch dams, but the slight curvature would increase the factor of safety by eliminating the tension in the horizontal beam; and combined beam, cantilever, and some arch action would support the load.

Whenever a load is supported on a beam, or on a cantilever, shearing stresses are introduced. These shearing stresses reach their maximum values at the foundation and at the abutments, and should be investigated in order to be sure that they are within safe limits. In the case of the dam section shown in Fig. 7, base 70 ft., it can easily be shown that, even should the shear on the lower 50 ft. of the dam

correspond to the full water pressure, this stress would be entirely within the safe limit, amounting to approximately 4 000 lb. per sq. ft. where the dam joins the hillside and foundation. Along this joint the maximum unit compression generally exists. This compression is so much larger than the shear that actual shear cannot take place, as friction alone will prevent any tendency to sliding at the abutments. Crushing would have to take place before the actual sliding of any element could occur. A fair approximation of the magnitude of the actual shear forces along the joint between the dam foundation and abutments can be obtained in the following manner: Formulas 5 and 5*a* are both applied in order to find in what proportion the load is divided between arch action and curved-beam action toward the bottom. Suppose Formula 5*a* gives, say, half as much deflection as Formula 5 for the same load; then it is indicated that the curved beam carries twice as much load as the arch. In reference to this the factor, CC_c, in Formula 5 should be left out, as we are working close to the foundation, where the arch is short and thick, and where it is therefore necessary to use both Formulas 5 and 5*a*.

From Formula 7 the percentage of the total load carried by the initial axial stresses can be found, and from Formula 8, etc., the percentage of the remaining load (due to head, $H - h$) taken by the cantilever, can be determined. In the case of the dam shown in Fig. 7, this percentage was found to be 45.5, and there is, therefore, 54.5% (of $H - h$) left for the arch and curved beam. Out of this the arch takes $\frac{1}{3} \times 54.5\%$, and the curved beam $\frac{2}{3} \times 54.5\%$ if Formula 5*a* gives half as much deflection as Formula 5. The shear is caused by a force equal to $45.5 + \frac{2}{3} \times 54.5\%$ of the load that remains after that carried by the initial axial stresses (Poisson's ratio) has been subtracted from the total load. Another place where shear action exists is in a vertical plane at the foundation along the toe when the reservoir is full of water. The tipping in a down-stream direction of the loaded cantilever deforms the toe and forces it to make a depression in the foundation, and, as the rock foundation extends outside the concrete toe, shear will take place where the end of the toe tries to deform the foundation. This circumstance introduces additional foundation

pressure at the toe, but this increase is already included in the value as found from Formula 9, at least approximately.*

Before concluding the general discussion, the action of changes in temperature should be considered. As the ends of the arch are fixed to the abutments, the shortening or lengthening of the arch due to temperature changes either causes cracks to develop or forces the crown back and forth. In the constant-angle arch type the average crown deflection for the same amount of decrease or increase in length of arch is only about half of that required by the common arch type (see Curves *A* and *B*, Fig. 9), and the tension necessary to cause this deflection or pulling back of the cantilever, therefore, may not exceed the ultimate strength of the concrete, in which case no cracks would develop. In any event, cracks are not as likely to occur as in the common arch type of dam.

Practical Examples of Arch Dams.

Plates IX and X show the plan and section of the Salmon Creek Dam, 168 ft. high above the river surface, containing 52 000 cu. yd. of concrete, having 1.25 bbl. of cement and a small percentage of lime per cubic yard. The contours represent the actual condition of the site after excavation, and it is seen that the sides of the canyon form an unusually regular V. The crest width of the dam is approximately 550 ft., measured in a straight line, and the arch at this elevation subtends an angle of 113 degrees. Plate IX shows the location of the centers for various arch slices, 12 ft. apart in elevation, and the length of the corresponding up-stream radii and unit axial stresses are given in the table on Plate X. To provide better accommodation for the spillway, the curve for the top 12 ft. of the dam was struck from the same center, therefore the warping of the faces commences 12 ft. below the crest, and continues down to the foundation. This warping is so uniform that one who does not know that the centers are moved constantly in an up-stream direction toward lower elevations does not notice it. The carpenter gets his points about every 10 ft. apart, and it makes no difference to him whether he builds up the

*The result from Formula 9 depends on Formula 8, and in Formula 8 the deflection due to the bending only is considered, not the additional deflection due to the horizontal shear forces accompanying the bending action, which amount to 10% (average), therefore the proportion of load taken by the cantilever, as given on page 1302, is really 10% too high, but this makes the resulting foundation pressure at the toe, found from Formula 9, more nearly correct on account of the action of the vertical shear at the toe, and this is the information that concerns the designer most.

face of a cylinder or an inverted cone (approximately). The surveyor, however, has to be more careful than with the layout of an ordinary arch, as, in the present case, there are more calculations to be made and to be followed.

The table on Plate X shows that the length of the longest up-stream radius is 333 ft., and the length of the shortest 147.5 ft., the ratio between the two being $\frac{333}{147.5} = 2.26$.

Had the length of the up-stream radius been kept constant, the thickness of the dam at the bottom would have had to be increased 2.26 times for the same axial stresses. Relative to this it should be noted that the arch stresses in the table assume the arch to take the total load, but in reality the stresses are somewhat smaller, as the cantilever takes part of the load. The triangular piece, 10 ft. wide at the bottom (which is added to the lower part of the dam on the down-stream side for the purpose of stiffening the cantilever where it is highest), is not considered in the table giving the arch stresses.

To have kept the enclosed angle (113°) constant at all elevations would have necessitated a greater ratio than 2.26 between the length of the two up-stream radii already referred to. Had this ratio been increased, the structure would have been overhanging in places, and therefore this increase could not be made. This simply shows that it is not always possible to make theory and practice coincide exactly.

To have kept the subtended angle constant in this case would have necessitated a greater bottom width of the site, other conditions remaining the same, but, of course, the dam has to be fitted to the site, and not *vice versa*. This dam creates a reservoir having a capacity of 826 000 000 cu. ft. The drainage area is only 7.5 sq. miles, but the precipitation makes up for it, being more than 100 in. per year.

Plate X shows a plan and section of the construction plant, and is self-explanatory. This construction plant, which proved to be the best kind that could be used for this particular place, was laid out under the supervision of Mr. H. L. Wollenberg, who was Chief Engineer of the Alaska Gastineau Mining Company, Juneau, Alaska, the owners, and had charge of this and other work. F. G. Baum, Assoc. M. Am. Soc. C. E., was Consulting Engineer for the Mining Company. The original design of the dam was made by the writer. Plates IX and X, however, were made by the Gastineau Mining Company.

F. C. Herrmann, M. Am. Soc. C. E., Chief Engineer of the Spring Valley Water Company, San Francisco, A. P. Davis, M. Am. Soc. C. E., Chief Engineer of United States Reclamation Service, and the writer visited and reported on the project at various times, and Mr. Herrmann wrote an extensive report thereon.

Figs. 10 to 13, inclusive, show different construction features, thus: The double tower with the two hoppers from which the two concrete chutes distribute the concrete over the dam. These chutes are supported on triangular wooden towers, easily removable. Two ¾-cu. yd. Smith mixers were used, and the progress was at the rate of about 400 cu. yd. daily. Work was shut down for the winter about November 1st, 1913, at which time the dam was half completed. It is expected to have it finished by August 1st, 1914. Indications are that the unit cost will be $7.50, or slightly less, including everything. The electric power plant, depending on the reservoir for its steady supply, is now in operation. Mr. D. C. Jackling is Vice-President, in charge of the operations of the Gastineau Mining Company, and Mr. B. L. Thane is Manager, with offices in Juneau, Alaska.

Plate XI shows the constant-angle arch principle applied on the Lake Spaulding Dam. This dam is part of the South Yuba development, undertaken and owned by the Pacific Gas and Electric Company, San Francisco, Cal.* The lower portion of this dam (60 ft.) is provided with a gravity section for a 260-ft. head, and is arched in plan, the length of the up-stream radius being 600 ft. up to Elevation 4 628. When this elevation was reached (less at the down-stream face, as shown on Plate XI) work was shut down for the winter, 1912-13. During the winter the original plans were changed, and in the following summer the dam was continued to Elevation 4 825, according to the plans on Plate XI. At Elevation 4 628 the length of the up-stream radius was changed from 600 ft. to 250 ft. and kept at this length up to Elevation 4 675. From this level up to the crest, the length of the up-stream radius increases so as to keep the subtended central angle as constant as possible, as shown by the table on Plate XI. This subtended angle is not as large as could be desired, but is as great as the

*This development has been described in detail in articles in *Engineering News*, *Engineering Record*, and others during 1913. Probably the most complete and accurate article on the subject is that written by R. W. Van Norden, M. Am. Soc. C. E., in the *Journal of Electricity, Power and Gas*, San Francisco, December 13th, 1913.

site would permit, considering that the ultimate proposed crest elevation is to be at Elevation 4 905.

The Lake Spaulding Dam is provided with an inspection tunnel, a drainage system, and contraction joints, which are usual features in dams of large proportions. The details of these features are shown on Plate XI. The section of the arch above Elevation 4 660 is of such dimensions that it will stand an extension of 35 ft. in height above the present crest elevation (4 825) without any addition to its thickness. The maximum arch stress (q in Formula 1) will exist at Elevation 4 775 with the water level at Elevation 4 860, or 260 ft. above the river bed, and will amount to 23.8 tons. It is fairly constant over the greatest portion of the structure, as can be seen from the table on Plate XI.

When the time comes to extend the crest of the dam to Elevation 4 905, 305 ft. above the river bed, a slab of concrete must be added to the down-stream face, and, in order to effect a good bond between the present dam and the new slab, the down-stream face of the present dam has been stepped off and a sufficient number of iron rods have been left protruding several feet to grip the new slab and hold it in place.

The Lake Spaulding Dam was constructed of a wet mixture of gravel concrete. Toward the top this mixture was richer than at the bottom, and contained from 1.17 to 1.25 bbl. of cement per cubic yard. Test specimens were broken every day, and the results of these tests were used as a guide in fixing the exact proportion of the mix. It was required that the breaking strength of the test specimens (8 in. in diameter) should be at the rate of 400 lb. per sq. in. when 7 days old; and 900 lb. per sq. in. when 28 days old. Toward the lower elevations, where the arch was thick, the mixture was somewhat leaner. The concrete was mixed in four 1-cu. yd. Smith mixers on the hillside above the dam, and, after being turned in the mixers for 1½ min., it was run by gravity in flumes to different portions of the dam, as shown on Figs. 14 and 15. After the dam had risen to a certain height the concrete could flow no more by gravity to portions farthest away, and a 30-in. belt-conveyor system was installed. With this system, all portions of the dam could be reached. There were also two cableways, to transport lumber and other materials to the dam. During the latter part of 1913 there was

very little water in the reservoir, the outside temperature was low, and the chemical heat was practically out of the dam body. This had the effect of opening up the contraction joints (which are 80 ft. apart) about $\frac{1}{8}$ in. In addition to this, cracks about $\frac{1}{16}$ in. wide, appeared midway between each contraction joint. These were all along radial lines, the same as the contraction joints. When the water in the reservoir rose to the crest, early in February, 1914, these cracks closed.

The outlet works from the reservoir consist of two intake tunnels (shown on Plate XI), concrete lined, and of a finished diameter of 8 ft. 8 in. One intake is at Elevation 4 670; the other is 100 ft. above. Each intake is provided with a 72-in. butterfly valve. The upper intake slopes downward about 48° until it meets the lower tunnel, this slope starting a few feet back of the upper butterfly valve. About 1 000 ft. down stream the single pressure tunnel ends in an adit, and is there provided with a second butterfly valve and also with two pressure reducers. Later, it is intended to install a 5 000-kw. turbine and let this act as a pressure reducer by utilizing whatever head there may be in the reservoir. From this point the 350 sec-ft. of water will flow by gravity toward the power-houses below, of which one is built, and four more are projected. After the water has left the lowest power-house, it will be used for irrigation.

The actual construction work was started under the direction of the late James H. Wise, Assoc. M. Am. Soc. C. E. It was continued and completed to date with F. G. Baum, Assoc. M. Am. Soc. C. E., as Chief Engineer. John R. Freeman, A. P. Davis, and H. F. A. Schussler, Members, Am. Soc. C. E., and others acted as Consulting Engineers at different times. Mr. Freeman, working in conjunction with Mr. Davis, made an extensive report, and many of the details suggested by these gentlemen are incorporated in the construction of the dam. Mr. Davis visited the site several times during the construction period. In the actual design as used, the writer's arch theory, and the shape of the up-stream face suggested in designs submitted by him, have been followed, except near the foundation, where an ordinary conical face was substituted below Elevation 4 675, instead of continuing the inverted cone (approximately) above.

Mr. John A. Britton was General Manager and Vice-President of the Company, H. C. Vensano, Assoc. M. Am. Soc. C. E., Civil Engineer. R. G. Clifford, Assoc. M. Am. Soc. C. E., Designing Engineer

and Resident Engineer when the dam was started. Mr. P. Magerstadt was Resident Engineer during 1913, and Messrs. Duncanson and Harrelson superintended the construction.

An arch dam 30 m. (98.4 ft.) high, with a base width of 4 m. (13.12 ft.) and a crest width of 1 m. (3.28 ft.), having an up-stream radius of 20 m. (65.6 ft.) at the bottom and 35 m. (114.8 ft.) at the crest, has been designed and built by H. F. Cameron, M. Am. Soc. C. E., Division Engineer of the Bureau of Public Works, Manila, P. I., to store water for domestic use.*

Fig. 17 shows a small diverting overflow dam designed on the constant-angle arch principle. It is built at an elevation of 13 000 ft. above sea level, in the Peruvian Andes, and is part of a hydraulic development by the Cerro de Pasco Mining Company. Messrs. F. G. Baum and Company, of San Francisco, were the engineers, and Mr. H. L. Wilcox was the Superintendent. This dam is designed to take care of a maximum overflow of 1 500 sec-ft., and is 62 ft. high, from bed-rock to crest, but only 24 ft. high above the river bed. The length of the up-stream radius at the crest is 36 ft., and at the river bed, 18 ft.

SUBAQUEOUS HIGHWAY TUNNELS.

By George Duncan Snyder, M. Am. Soc. C. E.

To be Presented September 16th, 1914.

Synopsis.

The object of this paper is to call attention to the use of tunnels as a means of crossing rivers or bodies of water by highways, particularly when the waters are navigable, and to discuss the conditions where tunnels are most suitable and where not.

The relative advantage of ferries, movable bridges, swinging draw-, bascule-, lift-, and transporter-bridges, are discussed, and a table showing the general dimensions of the principal transporter-bridges, is given. The suitability of pontoon bridges is considered, and also the relative advantages of fixed bridges and tunnels, and there is a table showing the general dimensions and cost of the principal bridges over navigable waters. The paper contains a history and description of existing subaqueous highway tunnels, including the Thames, Blackwall, and Rotherhithe Tunnels, in London, the Washington Street, La Salle Street, and Van Buren Street Tunnels, in Chicago; the Glasgow Harbor Tunnel, and the Hamburg Tunnel; and a table gives their general dimensions.

Projects for subaqueous highway tunnels at New York, Boston, Chicago, Sydney, Liverpool, and Oakland, Cal., are considered. Methods of construction are discussed, which include rock tunnels,

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

and, owing to their bearing on the subject, the Severn railway tunnel and the Mersey railway tunnel are described. Shield and compressed-air methods are described, as well as roof-shield, cut-and-cover, inside coffer-dam, and special methods, such as those used in the Harlem River crossing of the New York subway and the Detroit Tunnel. The caisson method used in Paris is considered, and also the freezing method.

Various types of lining—cast iron, brick, concrete, wrought steel, etc.—are described.

The shape of the section, means of access by inclines or shafts, methods of water-proofing, ventilation, and drainage, are also dealt with.

Conclusions.

The paper is a compilation of the available facts relative to subaqueous highway tunnels and other subaqueous tunnels applicable to highway purposes, and the conclusion is that, owing to the development of great harbors and the consequent need for unobstructed waterways and the increasing use of motor-driven vehicles, highway tunnels have not received sufficient consideration and are worthy of more extended discussion and attention.

Introduction.

With the growth of sea-borne commerce and its concentration at great ports, the problem of crossing harbors and their tributary navigable waters has become serious. The land traffic in the vicinity of a great harbor naturally develops with the water traffic, and inter-communication for land vehicles between the sides of a land-locked harbor is essential. The motor truck is being developed very rapidly and, if adequate facilities for inter-communication are provided, will develop still more rapidly and furnish a means of transferring goods from ocean vessels to railways, warehouses, and the like, thus relieving the small harbor craft and the railways from the burden of this transfer.

Where the harbor is not crowded, and with a low range of tide and a comparative freedom from fog and ice, a steam ferry is a fairly satisfactory means of crossing, as there are no excessive gradients of approach and the motors are idle or the horses resting while crossing. If, however, the harbor is crowded with water craft, there are two lines of traffic crossing each other's path on the same plane, or what in

railway parlance would be called a level or grade crossing, the avoidance of which would necessitate an under or over crossing, either by a tunnel or a bridge. With a great range of tide, it becomes difficult to load and unload boats, on account of the length of adjustable ramp necessary to avoid excessive gradients. With fog, ice, and bad weather, the danger of collision is increased, and the delays in loading, unloading, and operating ferries are serious, all of which add greatly to the cost of trucking.

On comparatively narrow channels, movable bridges of various sorts are used, but these do not avoid altogether the level crossing, as only the smaller craft can pass without having the draw-span opened. Many similar bridges are now being built at a level which will permit tugs and harbor craft to pass under them and thus decrease the frequency of opening. A clear space of 30 ft. from the surface of the water to the lowest member of a bridge will permit most harbor craft to pass under.

With a swinging draw, the large pivot pier required is a serious obstruction to the channel, and the maximum width of waterway, allowing for piers and fenders, is about 200 ft.* With a two-leaf bascule draw, the maximum span is about 300 ft. A lift-bridge has been built at Portland, Ore., with a span of 245 ft. and a clear headway of 135 ft. It will thus be seen that, at the best, such bridges interfere with the navigation of the waterway and fail to provide the free channels that an ocean port should have; also, the frequent opening of the draw obstructs the highway, and there is always the danger of a vessel colliding with a bridge.

Where the land traffic is light, transporter-bridges have been built. These are adapted to conditions where storms make the water very rough and cause difficulties in ferry navigation, or where the stream is obstructed at times by floating ice, or where a great fluctuation in the height of the water makes the design and construction of suitable landing ramps difficult. In general, they are erected at points where the importance of the river traffic is such that it cannot be hampered by a draw-bridge, where the traffic is so light as not to warrant the building of a fixed bridge or tunnel, or where the physical difficulties in the construction of a bridge or tunnel are very great.

* A swinging draw-bridge is to be constructed at Vancouver, B. C., with a length of 581½ ft. between end bearings; this will be the longest in existence and will have a clear width of waterway of 225 ft. (*Engineering News*, February 19th, 1914.)

Table 1 gives the general dimensions of the principal transporter-bridges.

TABLE 1.—TRANSPORTER-BRIDGES.

Location.	River.	Span, in feet.	Clear height, in feet.

Bizerte (near Tunis, Africa)		357.63	147.65
Brest, France	(Harbor)	357.6	144.4
Osten, Germany	Oste	262.5	83.8

It will be seen from Table 1 that the longest span is 1 000 ft., between Widnes and Runcorn,* over the Mersey, shown by Fig. 1. The only example in America is at Duluth, with a span of 393.75 ft.†

Most of the transporter-bridges in Table 1 are over harbors, canals, arms of the sea, or inland waters, and practically no through highway for ocean-going vessels is spanned by such a structure. There are many places where no other form of construction is warranted by the traffic; but, at the best, transporter-bridges are only suitable for comparatively narrow channels, where neither the water nor land traffic is heavy, and not for the crowded conditions of a great ocean port.

Pontoon bridges, with movable sections which can be floated to one side to permit the passing of boats, have been built. Such bridges are generally used in sparsely settled regions, where the land traffic is light; they are more or less temporary in character, and are a cheap substitute for a more permanent structure where the traffic does not warrant the heavier expenditure. However, a bridge of this type, crossing the Golden Horn, at Constantinople, which is more permanent in character, has recently been completed. The length between abutments is 1 530.84 ft., and the width of roadway, 82 ft. For small boats there are two spans of 39 ft. having a clear headway of 17½ ft., and a draw section with a clear opening of 205 ft.‡

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXV, p. 87.
† *Transactions*, Am. Soc. C. E., Vol. LV, p. 322.
‡ *The Engineer*, December 6th, 1912.

Numerous bridges of this type have been built in India.* In Calcutta one has been designed with submerged pontoons anchored at a fixed level so as to avoid the change in level of the roadway with the fluctuations of the water surface.†

Several pontoon railroad bridges of considerable length have been used in America. One, with a draw section 405 ft. long, was built at Prairie du Chien, Wis., in 1874, by the Chicago, Milwaukee and St. Paul Railway Company; this company also had four other bridges of similar type. These bridges, instead of being separate pontoons acting as piers, were really continuous floating structures.

Bridges of this type are not suited to a busy harbor frequented by numerous ocean-going vessels, and where there is a heavy land traffic.

The only remaining alternatives are fixed bridges at sufficient height to clear the shipping, or tunnels or passages at a greater depth than the draft of the vessels.

In avoiding the level crossing of these two conflicting kinds of traffic, by placing the roadway above or below the water, there is an advantage in depressing it, as the top of the structure need only be about 40 ft. below low water; whereas, if elevated, the bottom must be from 135 to 175 ft. above high water. This paper, however, is not written with the view of entering into a controversy as to the relative merits of bridges and tunnels, as no general law can

be laid down; each problem must be decided on its merits in accordance with the conditions.*

Where the conditions are favorable for a bridge, there is no doubt that it is the most desirable means of crossing a body of water. These favorable conditions are high banks, which reduce the length and gradient of the approaches; moderate spans; a suitable stratum for the support of foundations at a reasonable depth; cheap land for approaches; and the ability to place piers so that they will not interfere with navigation. When the spans must be in excess of 1 000 ft., when proper support for foundations can only be had at a great depth, or when the land near the water is low, the conditions favor a tunnel. When bridges exceed a span of 1 000 ft., they must be given considerable width, for lateral stability, and the dead loads being so great, the bridges can be given great capacity by the addition of rapid transit and street railway tracks without adding greatly to the expense. This causes an undue concentration of traffic at the ends of such bridges and adds greatly to the difficulty and cost of the terminals. In other words, instead of building a bridge with

capacity to suit the needs of the traffic, or several bridges located so as to suit the convenience of the public, economical considerations necessitate the construction of a single large bridge, either of greater capacity than required, or which concentrates the traffic along a single path that would be better served by several.

One other point should be given due consideration, and that is the relative ease of destruction of a bridge, as compared with a tunnel. The severing of a single member would cause the collapse of a whole span. Although injury at a single spot might cause the flooding of a tunnel, the damage would be local and could be readily repaired. This is mentioned in view of the fact that national wars have not altogether ceased, and that those who disapprove of existing conditions sometimes express their dissatisfaction by the use of explosives.

Table 2 shows the general dimensions of some of the world's principal bridges crossing waters frequented by seagoing vessels. This table does not purport to be exhaustive, but merely gives typical examples of the most important bridges of the various classes, some being included merely on account of their historical significance. The physical conditions are such at certain of the bridges in Table 2

that a tunnel could not readily be substituted; at the Forth Bridge, on account of the great depth of water, which is more than 200 ft.; at the connecting railroad bridge at Hell Gate, for the same reason; at the Poughkeepsie Bridge, Washington Bridge, High Bridge, etc., on account of the height of the river banks. On the other hand, at many of the other bridge locations, in view of the modern state of the art, tunnels could be constructed more advantageously than bridges.*

Highway Tunnels: History.

London.—It is a curious fact that one of the first subaqueous tunnels, and the first on which a shield was used, was constructed as a highway tunnel, but was never used for that purpose. This was the first Thames Tunnel, built by the inventor of the shield, the late Sir Marc Isambard Brunel. His patent for a shield was No. 4 204, of 1818. Owing to London Bridge marking the head of navigation for seagoing vessels, the development of the docks and tributary industries was necessarily below this point, so that the need of some means of crossing the river below London Bridge is evident. This is indicated in Fig. 2, which shows the position of the Tower Bridge and the various tunnels below London Bridge. The Thames Tunnel, Fig. 3, crosses the river between Rotherhithe and Wapping, about 1½ miles below London Bridge. Work was started in 1825 and, after being suspended several times owing to physical and financial difficulties, was completed in 1843. In section it is one of the widest openings ever constructed, the total width of excavation being 37 ft. 6 in., and in height 22 ft. 3 in., separated by a wall 4 ft. thick, pierced by 64 arched openings, each of 4 ft. span. The length is 1 200 ft. It was proposed to have spiral approaches, but this was never done; the construction shafts, however, were fitted with stairways. In 1866, the tunnel was sold to the East London Railway Company, and since that time this company has operated its trains through it. Its cost, including shafts, was £1 300 per lin. yd.

As the Thames Tunnel had been diverted from its intended use, the vehicular traffic still had no facilities below London Bridge, but its needs were partly met by the Tower Bridge, about ½ mile below

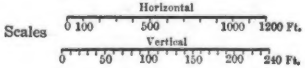

FIG. 5.

the tunnel was opened to traffic in 1897. It consists of a shield-driven, iron-lined tunnel (Fig. 6), 27 ft. outside diameter, with an internal diameter of 24 ft. 3 in. It is lined with concrete faced with glazed tile, has a roadway 16 ft. wide, and two foot-paths, each 3 ft. 1½ in. wide. The total length, including approaches, is 6 200 ft.; the length from portal to portal is 4 465 ft.; and the length under the waterway is 1 220 ft. The maximum gradient of approach is 1 in 36. Changes in direction were not made by driving the tunnel in curves, but by angles at the shafts. The cost was £871 000, amounting to about $685 per lin. ft.

The Rotherhithe Tunnel,* Fig. 5, was commenced in 1904 and completed in 1908. It crosses the river diagonally from Rotherhithe to Ratcliff, about 2¼ miles below London Bridge. The work was very similar to that at the Blackwall Tunnel. It is a shield-driven, iron-lined tunnel, with an external diameter of 30 ft. and an inside diameter (inside the concrete and tile lining) of 27 ft. It is provided with a roadway 16 ft. wide, and two walks, each 4 ft. 8½ in. wide. Figs. 8 and 9 show the Stepney Approach, and the spiral stairs at Shaft 2, Rotherhithe. The total length, including approaches, is 6 883 ft.; the length from portal to portal is 4 930 ft.; and the length under the waterway is 1 480 ft. The cost was £1 088 484, or about $930 per lin. ft.

Chicago.—In the United States the first subaqueous highway tunnel was the Washington Street Tunnel, crossing the Chicago River, in Chicago.† (Fig. 10.) This is not properly a tunnel at all, but a subaqueous passage built in an open trench between coffer-dams. It was built by the City of Chicago in 1866 to 1869, and had two roadways, each 11 ft. wide and 13 ft. high, and a footway 10 ft. wide and 10 ft. high, as shown by Fig. 11. It was at first used quite extensively for general highway traffic, and, after the fire in 1871, was the only means of communication between the west side and the business district, for some time, until the burned bridges could be restored. Incidentally, a tunnel is less likely to be damaged by fire or flood than is a bridge. This tunnel, later, fell into a bad state of repair and was used much less frequently, the traffic being largely diverted to the nearby bridges. At the time of the change of power from horse

FIG. 7.

to cable on the Chicago street railways, permission was obtained to utilize the tunnel, one of the conditions being that the roof be lowered so as to give a depth of 17 ft. of water in the river, instead of 14 ft. This use of the tunnel was desirable, as the difficulties of operating a cable railway over a movable bridge were great. Since the substitution of electric traction for the cables, the tunnels are not so necessary, but the advantages of uninterrupted service still remain. The tunnel roof was lowered in 1889, the cost being about $135 000. This work was done by enclosing the tunnel between coffer-dams—only one-half of the river being obstructed at one time. The masonry arched roof was removed and replaced with 20-in. steel I-beams, 36 in. apart, with jack-arches between. At the same time, the dividing wall between the two roadways was removed and the tunnel was given a single opening of 20 ft. clear span. The invert was also cut out and lowered 2 ft. 6 in. in order to provide the necessary headroom. The use of the tunnel by vehicles and pedestrians was discontinued; a draw-bridge was constructed nearby; and the footway was used as a pipe gallery. In 1906 the tunnel was again reconstructed, in order to provide a navigable depth of 26 ft. instead of 17 ft. This was accomplished by cutting chases in the walls and inserting 33-in. plate girders, 48 in. apart, supporting a new masonry roof, after which the old roof was removed by breaking it up, without blasting, and dredging from the exterior. The side-walls were then underpinned and a new invert was constructed, as shown by Fig. 12. In 1909 further alterations were made in order to enable the tunnel eventually to form part of a subway system in the business district, and this necessitated building temporary inclined approaches to enable the surface cars to continue the use of the tunnel, pending the construction of the subway system. The cost of this work was about $675 000.

La Salle Street Tunnel (Chicago).—The construction of the original La Salle Street Tunnel was commenced by the City of Chicago in 1869, and it was opened for traffic on July 4th, 1871. The type of construction was similar to that of the Washington Street Tunnel. The total length is 1 887 ft., and the gradients of approach are 1 in 20. In section, it consisted of two roadways, each 11 ft. wide, and a footway 11 ft. wide and 10 ft. high, as shown by Fig. 13. The original cost was $566 000. The tunnel was given over to cable-operated street cars in 1889.

FIG. 11.

In 1906 work on the lowering of the roof, in order to increase the navigable depth of water from 18 to 26 ft., was commenced. It was intended to follow a method similar to that used for the Washington Street Tunnel. Inside the tunnel, 30-in. steel girders were to rest on the old west wall, and a new brick wall was to be placed inside the old footway, the latter being retained as a pipe gallery. Owing to the development of excessive leaks in executing this work, the tunnel was flooded and a change of plan was made. A method of doing the work by enclosing sections in coffer-dams was considered, but, as the United States Government engineers would not permit coffer-dams for a distance of 60 ft. from the dock lines, it was necessary to devise some other plan. The method adopted was to construct

two parallel steel cylinders, each comprising about 75% of a circle, with a common longitudinal stiffening truss. This shell was built at a dry dock, and was 278 ft. long, 27 ft. high, and 41 ft. wide. It was made up of $\frac{3}{8}$-in. plates, 7 ft. 6 in. wide, and 19 ft. long, stiffened by Z-bars and plate and angle gussets. The concrete for the invert and center wall was placed while the shell was in the dry dock, as were the timber bulkheads in each end, and the temporary internal bracing, as shown by Fig. 14. The weight of the steel in the tubes was about 500 tons, and the total weight when first floated was about 3 000 tons. After floating, the shell was towed to near the site of the tunnel. Internal concrete was then added until the tops of the tubes barely projected above the water, the total displacement being 7 852

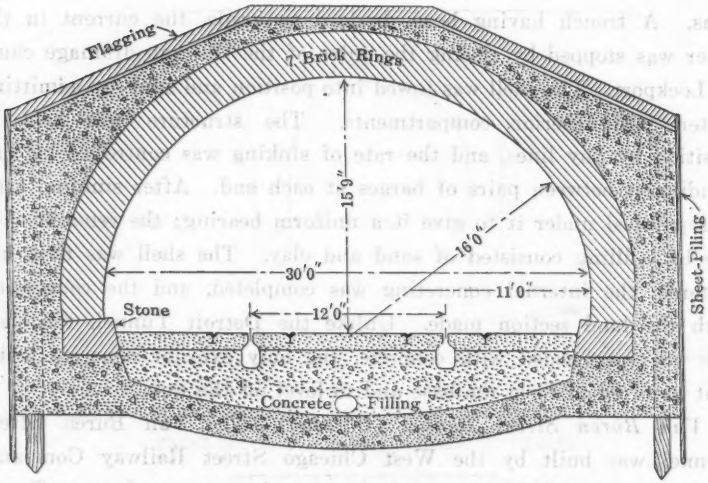
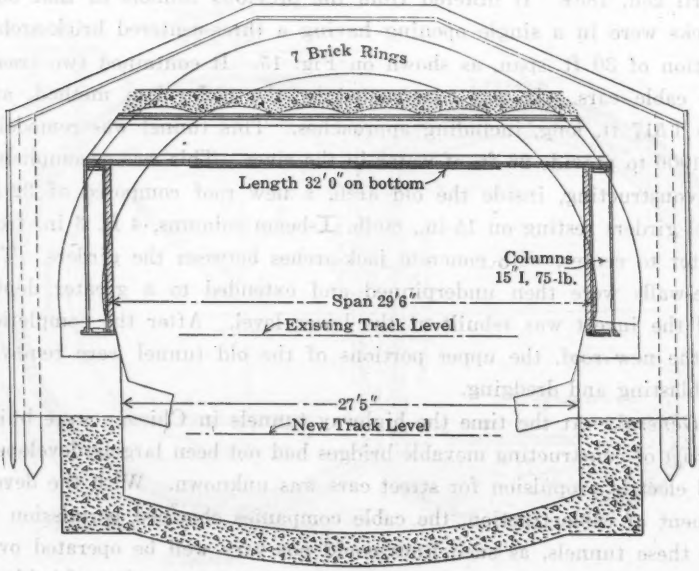
tons. A trench having been dredged to grade, the current in the river was stopped by closing the gates of the Chicago drainage canal at Lockport. The shell was towed into position and sunk by admitting water into interior compartments. The structure was held in position by guy lines, and the rate of sinking was controlled by suspending it between pairs of barges at each end. After sinking, sand was pumped under it to give it a uniform bearing; the remainder of the back-filling consisted of sand and clay. The shell was then unwatered, the internal concreting was completed, and the connection with the land section made. Unlike the Detroit Tunnel, the shell was not surrounded with concrete, the only exterior concrete being that required to form the base and to level off the top.

Van Buren Street Tunnel (Chicago).—The Van Buren Street Tunnel was built by the West Chicago Street Railway Company. Work was started in 1889, and the tunnel was opened to traffic on April 23d, 1894. It differed from the previous tunnels in that both tracks were in a single opening having a three-centered brick-arched section of 30 ft. span, as shown on Fig. 15. It contained two tracks for cable cars. It was constructed by the coffer-dam method, and was 1 517 ft. long, including approaches. This tunnel was remodeled in 1906 to provide 26 ft. of water in the river. This was accomplished by constructing, inside the old arch, a new roof composed of 32-in. steel girders resting on 15-in., 80-lb. I-beam columns, 4 ft. 3 in. from center to center, with concrete jack-arches between the girders. The side-walls were then underpinned and extended to a greater depth, and the invert was rebuilt at the lower level. After the completion of the new roof, the upper portions of the old tunnel were removed by blasting and dredging.

General.—At the time the highway tunnels in Chicago were built, the art of constructing movable bridges had not been largely developed, and electric propulsion for street cars was unknown. With the development of cable traction, the cable companies obtained permission to use these tunnels, as such lines could not very well be operated over movable bridges. At the same time, the increasing number of bridges, together with improvements in the mechanism for operating them—which reduced the delays due to the draw being open—and the avoidance of the heavy gradients of the tunnel approaches, led to their



CROSS-SECTION, ORIGINAL VAN BUREN ST. TUNNEL



CROSS-SECTION, FINAL VAN BUREN ST. TUNNEL

FIG. 15.

diminishing use by vehicular traffic, and finally to their being turned over exclusively to the street-car lines.

The original Washington Street Tunnel was in very leaky condition from the beginning, and in the winter great trouble was caused by the formation of ice—so much so, that in severe weather the accumulation of ice and icicles could not be removed fast enough, and the tunnel had to be closed to traffic.

Glasgow.—In Glasgow, a tunnel for vehicles was constructed across the Clyde in 1890-93. Access to this tunnel, instead of being obtained by inclined approaches, is by elevators in shafts. The tunnel consists of three separate cast-iron tubes, each having an internal diameter of 16 ft., the center tube being used as a footway and the outer ones for vehicles, each in a single direction. Fig. 16 shows the profile. The footway tube has inclined approaches and stairs. The shafts are circular, 76 ft. inside diameter, and 80 ft. outside diameter. The river is 415 ft. wide, and the length of the tunnel from shaft to shaft is 700 ft. This tunnel was constructed by private capital, but, owing to competition by a municipal ferry, its use has been discontinued. It is now, however, proposed to re-open it, the City Corporation having arranged with the Glasgow Harbor Tunnel Company to operate it for a period of one year after the date of re-opening, on condition that, on the expiration of that time, the Corporation shall have the option of purchasing the whole undertaking for £100 000, although the original cost was £287 000.*

Hamburg.—A highway tunnel, Fig. 17, very similar to that at Glasgow, has just been completed under the Elbe at Hamburg.† Access to this tunnel is also obtained by elevators in shafts, and the total length from center to center of shafts is 1 471 ft. Each shaft (72 ft. inside diameter and 84 ft. outside), contains four elevators for vehicles and two for foot passengers. The lift of the elevators is 78 ft. The lining is composed of structural-steel plates and angles, the outer diameter being 19.7 ft. It has a lining of concrete and tile, and the roadway is only wide enough for a single vehicle, there being a separate tube for traffic in each direction. Fig. 18 is a cross-section. The general dimensions of the subaqueous highway tunnels of the world are given in Table 3.

* *Engineering*, May 10th and 31st, June 14th and 28th, 1895, contains a description of the shafts, lifts, etc.

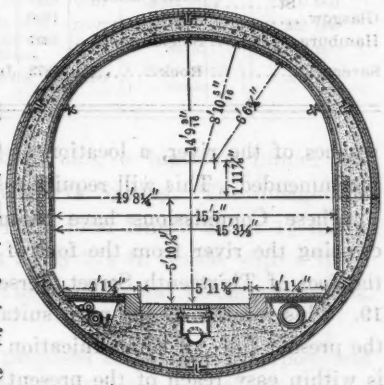
Projects.

From the preceding it will be seen that highway tunnels have not had a very fortunate history. The Thames Tunnel, the first ever built, was never utilized for the purpose intended, but was first used by a steam railway, and now by a railway operated by electric power. The tunnel, however, is now performing a useful function, and is practically in as good condition as when completed, 70 years ago, carrying more vehicles, each of much greater weight, than was contemplated originally, and it is not probable that as much could be said of a bridge, other than one of masonry.

The Chicago tunnels have had to be rebuilt to provide greater depth of water (one of them being rebuilt twice), and their use for general highway traffic has been discontinued. They are now being utilized only by the street cars.

The use of the Glasgow Tunnel has been discontinued, owing to municipal competition, and only the Blackwall, Rotherhithe, and Hamburg Tunnels remain in successful operation. Nevertheless, various projects are under consideration for the construction of highway tunnels, and therefore the subject is worthy of consideration.



CROSS-SECTION, OF ELBE TUNNEL AT HAMBURG

Fig. 18.

New York.—Some means other than ferries for vehicles to cross the Hudson (North) River at New York has long been needed. As the river forms the boundary between the States of New York and New Jersey, such means of crossing must be provided by the joint action of the two States or by a private corporation. This subject is now under investigation by the two States, through the medium of the New Jersey Interstate Bridge and Tunnel Commission and the New York Interstate Bridge and Tunnel Commission. These two Commissions have agreed that, if a bridge is to be built, it should be as far south as physical conditions will permit. As no suitable foundation can be obtained at points where piers would be permitted in the lower

reaches of the river, a location at about Fifty-eighth Street has been recommended. This will require a span of 2 880 ft.

These Commissions have recommended a location for a tunnel crossing the river from the foot of Canal Street, New York, to about the foot of Thirteenth Street, Jersey City, as shown on the map, Fig. 19. This location is the most suitable, as it is in the average path of the present lines of communication for vehicles crossing the river, and is within easy reach of the present bridges over the East River. The New York approach to such a tunnel will come to the surface at about the intersection of Varick and Canal Streets. Varick Street is now being widened, and will connect with the extension of Seventh Avenue, which is now under way.

The present traffic crossing the river at New York is about 20 000 vehicles daily.

Boston.—In Boston there has been some agitation for a highway tunnel from Boston to East Boston. Gen. J. G. Foster, when United States Engineer Officer at that port, in 1868, prepared a design for such a tunnel.

Chicago.—In Chicago it has been proposed to build a tunnel under the Chicago River in order to connect the Boulevard and Park System. Two tunnels, each 31 ft. in diameter, have been suggested.

Sydney.—At Sydney, New South Wales, a highway tunnel has been proposed to connect Sydney and North Sydney. The subaqueous portion would be 1 416 ft. long, and the total length about 1½ miles. The proposed section would be about 21 by 27½ ft. inside, with a 16-ft. roadway and two 4½-ft. walkways. The more recent recommendations, however, have been for a bridge.

Liverpool.—It has recently been proposed to connect Liverpool and Birkenhead by a tunnel under the Mersey for the use of vehicles and tram cars. As a successful passenger railway tunnel has been constructed under the river at this point, there would probably be no insurmountable physical difficulty in building a similar tunnel for highway purposes.

Oakland, Cal.—A tunnel has been proposed between Oakland and Alameda for a 20-ft. driveway and two 6-ft. suspended foot-walks.

METHODS OF CONSTRUCTION.

Existing highway tunnels have been constructed in soft ground by the shield method, by coffer-dam, or by sinking a metal form in a trench dredged from the surface, in which a lining of concrete was deposited; but, as other methods have been used successfully in build-

ing subaqueous tunnels for other purposes, they can be applied to the construction of highway tunnels where the conditions are favorable.

All the European examples are shield-driven. The first Thames Tunnel was driven without compressed air, but it was used on the Blackwall, Rotherhithe, Glasgow Harbor, and Hamburg Tunnels. In the United States, the Chicago tunnels were originally built within coffer-dams and afterward lowered by various means; in the La Salle Street Tunnel, a metal form was sunk from the surface.

Rock.—No subaqueous highway tunnels have been driven in rock formation, but several notable tunnels for other purposes have been constructed in rock, and there is no reason that they could not be built for highway purposes where the conditions are favorable. Both the Mersey and Severn Tunnels were driven in rock without the aid of compressed air. The Mersey Tunnel has an internal span of 26 ft. and a height of 23 ft. from the invert to the intrados. It is lined with brick masonry, and contains a double-track railway. It was opened on February 1st, 1886, and was first worked with steam locomotives and afterward by electricity. It is 3 960 ft. long between quay walls, and the total length of the line is 4.1 miles. It was excavated in sandstone, and the maximum depth of invert below mean high water is about 151 ft. Its cost, including equipment, was about £500 000 per mile.* Fig. 20 is a profile of this tunnel, and Fig. 22 is a cross-section.

Severn Tunnel.—The Severn Tunnel, Fig. 21, was excavated through conglomerate, carboniferous strata, sandstone, shale, and gravel. It is peculiar in that the width of the river at the point of crossing is 2¼ miles at high tide, but only 1 650 ft. at low water, the mean tidal range being 37 ft. Its total length is 4.36 miles. The maximum depth of the invert below high tide is 156 ft. The internal section of the tunnel is 20½ ft. high above rail level, and 26 ft. wide, and it is lined with brick masonry. The tunnel is notable on account of the difficulties encountered during construction. Water reached the workings through fissures and springs, the pressure from one spring being so great that it crushed the brickwork. This led to the sinking of an extra shaft at the site of the spring in which pumps were placed to remove the water and relieve the pressure. The total capacity of the pumping plant for the permanent drainage of the tunnel is

FIG. 21.

66 000 000 gal. per day, this being about twice the maximum quantity of drainage. The total cost of the tunnel was about £1 500 000.*

Various subaqueous tunnels have been constructed in rock for the conveyance of gas and water, some of these being at great depth, but the conditions of access are so different from those of a highway tunnel that they are scarcely comparable.

The conditions favorable to such tunnels in rock are where the strata are non-water-bearing, without faults or fissures, or where the depth of the water is beyond the maximum for work with air pressure. One advantage is that the tunnels can be given an economical cross-section more suited to their use than the circular form usually obtained with a shield.

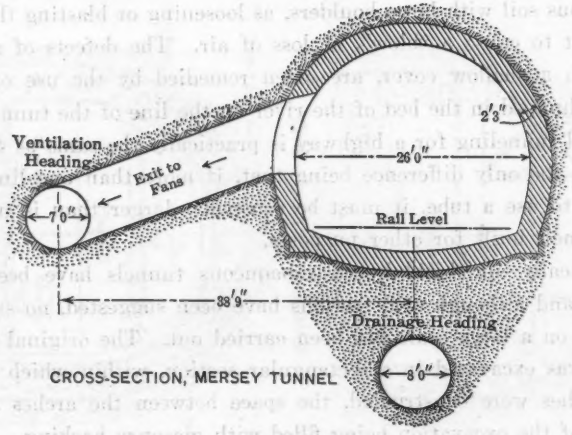

FIG. 22.

Shield Tunnels.—Four of the subaqueous highway tunnels have been driven in soft ground with a shield, and with the aid of compressed air. If the Thames Tunnel is included, there are five, but, in this latter case, compressed air was not used. Two of these tunnels (the Glasgow and the Hamburg), provide for a single line of vehicles in a tube, and two (the Blackwall and the Rotherhithe), provide two lines in opposite directions in a single tube, with a footway as well. The diameters of these tunnels range from 17 to 30 ft. A shield tunnel for a double line of electric railway has recently been completed under the Seine, in Paris, with a diameter of 25 ft. $6\frac{5}{32}$ in.

* "The Severn Tunnel," by T. A. Walker.

The conditions favoring the selection of the shield method of driving tunnels are: where the strata are of water-bearing silt, clay, sand, or gravel; where the bottom of the tunnel is not more than 100 ft. below the water surface; where a reasonable cover of material, between the top of the tunnel and the bed of the river, can be obtained; and where the channel of the waterway cannot be obstructed during construction. In suitable material very rapid progress can be made, the cast-iron lining facilitating rapid construction. On one tunnel of the Hudson and Manhattan Railroad, driven through Hudson River silt, a length of 72 ft. was built in one day.

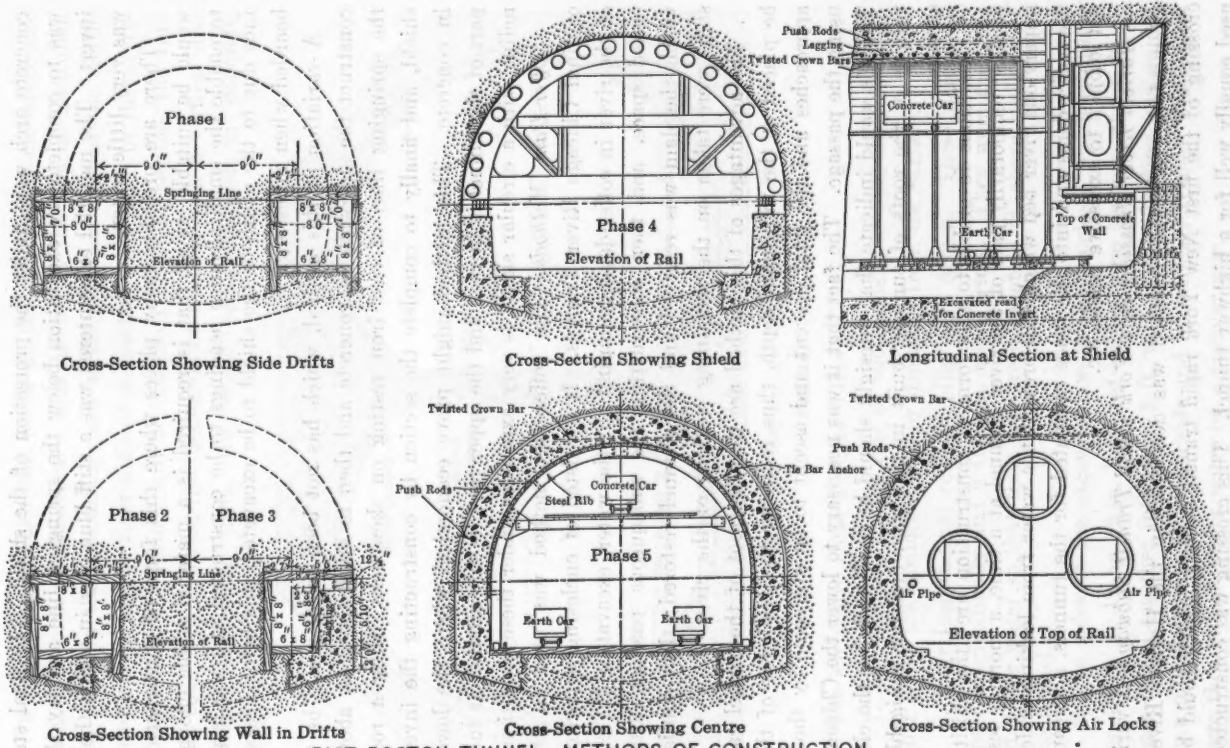
Shield construction is difficult when the lower portion of the tunnel is in rock and the upper portion is in silt or sand; it is also difficult in a porous soil with large boulders, as loosening or blasting the boulders is apt to cause a "blow", or loss of air. The defects of a porous soil, with a shallow cover, are often remedied by the use of a clay blanket dumped in the bed of the river on the line of the tunnel.

Shield tunneling for a highway is practically the same as for other purposes, the only difference being that, if more than one line of vehicles is to use a tube, it must be somewhat larger than is usual for such tunnels built for other purposes.

Practically all shield-driven subaqueous tunnels have been made circular, and although oval sections have been suggested, no such construction on a large scale has been carried out. The original Thames Tunnel was excavated in a rectangular section, within which the two brick arches were constructed, the space between the arches and the exterior of the excavation being filled with masonry backing.

Roof Shields.—No highway tunnels have been built with a roof shield, although this form of construction would give a more suitable section than a circular shield. A notable example of this form of tunneling is the East Boston Tunnel,* used by a double line of street cars. The internal span of this tunnel is 23.33 ft., with a height of 18 ft. above the rails. It was lined with concrete, which was about 3 ft. thick. The method of procedure, Fig. 23, was to excavate two small headings—one on each side—in which the sidewalls were constructed. This was followed by the shield, which rested on the sidewalls and was advanced by the jacks thrusting on push-bars embedded in the concrete. The excavation above the springing line and the

* Seventh Annual Report, Boston Transit Commission, August 15th, 1901.



EAST BOSTON TUNNEL. METHODS OF CONSTRUCTION.

FIG. 23.

concrete arch were under the protection of the shield. The final step was to complete the excavation below the springing line and lay the invert. The material encountered was a stiff blue clay in which there was very little water.

There are probably many places where this form of construction would be suitable, as all that is required is a material stable enough to enable the small advance headings to be constructed and the large face due to the width of the shield to be excavated, this being breast-boarded when necessary.

A variation of this method, which has not been tried, would be to construct the side-walls of concrete and then to build the roof, above the springing line, of cast iron resting on skewbacks, using a roof shield, and finally to complete the section by constructing the invert in concrete. This method might prove economical where the lower part of the tunnel is in rock and the upper part in soft ground, as tunneling with a circular shield is very expensive under these conditions.

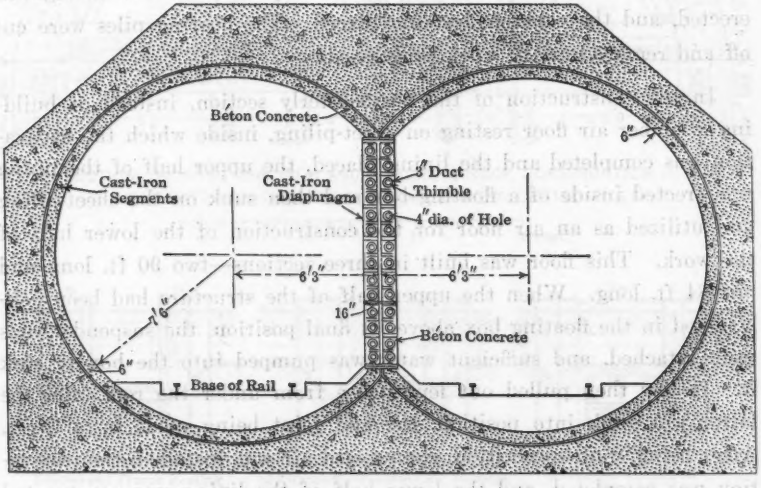
Coffer-Dam Methods.—The coffer-dam method was used in the original Chicago River Tunnels. It consisted of enclosing a portion of the river in coffer-dams, pumping out the water, excavating the enclosed space, and then constructing the subaqueous passage, after which the dam was removed and the channel restored; then similar steps were taken on the remaining sections of the river.

The advantages of this method are that the roof of the tunnel can be placed at the minimum depth, thus reducing the gradients of the approaches and the total descent and ascent to be overcome by those using the passage. The fact that it was necessary to lower the Chicago Tunnels would indicate that foresight should be used in fixing the elevations of the roofs of tunnels, built in this way, crossing navigable streams.

Conditions favorable to this form of construction are: the ability to close temporarily part of the river channel at a time, a more or less impervious river bed which will prevent the water from leaking under the coffer-dams and into the space excavated for the tunnels, a stream not subject to excessive floods, etc.

Harlem River Crossing, New York Rapid Transit Subway.—A variation of the coffer-dam method was developed in the Harlem River crossing of the first New York rapid transit subway, which could be used equally well for a highway tunnel. This crossing was constructed

in two sections, one-half the width of the river being closed at one time. The plan of construction was devised by the firm of McMullen and McBean, the contractors, and as the methods used in the southwesterly half of the river differed somewhat from those in the northeasterly half, the former will be described first. In section, the tunnels consist of two cast-iron segments of a circle with a vertical diaphragm separating them, the whole being encased in concrete. (Fig. 24.)



CROSS-SECTION, HARLEM RIVER TUNNEL

FIG. 24.

The successive steps were as follows:

1. The material on the line of the tunnel was excavated to somewhat below the springing line by dredging from the surface.

2. Four longitudinal rows of piles were driven. These were 8 ft. apart longitudinally and 6 ft. 4 in. transversely. They were then cut off under water so that their tops were about 11 ft. above the axis of the tunnel.

3. The sides of the excavation were then enclosed by sheet-piling, consisting of 12 by 12-in. long-leaf yellow pine timbers, about 65 ft. long, bolted together into units 3 ft. wide. This sheeting was guided by a pile platform along each side and by a timber frame. These piles were then cut off under water by a circular saw.

4. On top of the four rows of bearing piles and the sheet-piles, was then sunk a timber deck consisting of three transverse layers of 12 by 12-in. timbers and two longitudinal layers of 2-in. plank. After this was sunk accurately in place, it was covered with a thickness of about 5 ft. of earth and mud.

5. Several vertical shafts were placed, passing through this deck, and, after placing bulkheads at the ends and air locks, compressed air was turned on and the excavation was completed, the iron lining was erected, and the concrete backing placed. The bearing piles were cut off and removed as the work progressed.

In the construction of the northeasterly section, instead of building a timber air floor resting on sheet-piling, inside which the excavation was completed and the lining placed, the upper half of the lining was erected inside of a floating box and then sunk on the sheet-piling and utilized as an air floor for the construction of the lower half of the work. This floor was built in three sections—two 90 ft. long and one 84 ft. long. When the upper half of the structure had been constructed in the floating box above its final position, the suspender rods were attached, and sufficient water was pumped into the box to sink it. It was then pulled out lengthwise from under the roof, and the latter was sunk into position, the end joint being made by a diver. After being sunk to position, compressed air was installed, the excavation was completed, and the lower half of the lining was constructed (Fig. 25).

A design for the application of this method to a highway tunnel was prepared by the Carnegie Steel Company and presented in a paper by R. B. Woodworth, M. Am. Soc. C. E., before the Railway Club of Pittsburgh.* (Fig. 26.) This plan contemplates a roadway 60 ft. wide, with two electric car tracks, the floor and side-walks being of concrete and the roof of steel embedded in concrete.

Another design for a highway tunnel by this system, having two roadways, each 19 ft. 6 in. in width, was shown before the Hoboken Board of Trade on February 4th, 1913. (Fig. 27.)

Detroit Tunnel.—The method used in constructing the Detroit River Tunnel has been described so thoroughly in the paper† by W. S.

Kinnear, M. Am. Soc. C. E., and in the paper* by W. J. Wilgus, M. Am. Soc. C. E., that but little comment is necessary. Briefly, the method consisted of dredging a trench along the line of the structure into which were sunk sections of steel tubes which acted as forms to limit the concrete deposited from barges through tremies. These sections were 262 ft. 6 in. long. After the sinking, concreting, and joining of sections, they were unwatered and a lining of concrete was added. (Fig. 28.) The roof of this structure is 41 ft. below the surface of the water, and for some distance is above the bed of the river. The approaches were constructed with a shield, partly with and partly without compressed air.

The conditions favorable to this form of construction are: a material that can readily be dredged and that will enable the slopes of the dredged trench to stand at a fairly steep slope; a modest current, not subject to sudden fluctuations; and a channel, the obstruction of a portion of which at a time will be permitted.

Its advantages are that a structure can be placed at a higher level than with a driven tunnel, with a consequent reduction in the gradients of approach, and the section can be given a shape conforming to the use to which the tunnel is to be put, without being limited to the circular section usual with a shield.

Caisson Method.—Several sections of the tunnels of the Hudson and Manhattan Railroad Company were constructed in short lengths of reinforced concrete, which were sunk as pneumatic caissons. Three special switch enlargements were built in this way in Jersey City, and in these cases the tunnel itself formed the working chamber of the caisson. The approaches to the Church Street Terminal in Cortlandt and Fulton Streets, New York, were also constructed in this way, but here a special working chamber was built below the floor of the tunnel. However, the most notable example of this form of construction is that of the Metropolitan Railway, in Paris, which crosses the two arms of the Seine between Porte de Clignancourt and Porte d'Orleans.† In this case the larger arm was crossed by using three caissons, 118, 125.9, and 141.7 ft. long, respectively, and the smaller arm by two caissons, each 65.9 ft. long. Two stations under the land nearby were also constructed in this way. These caissons were sunk with a space

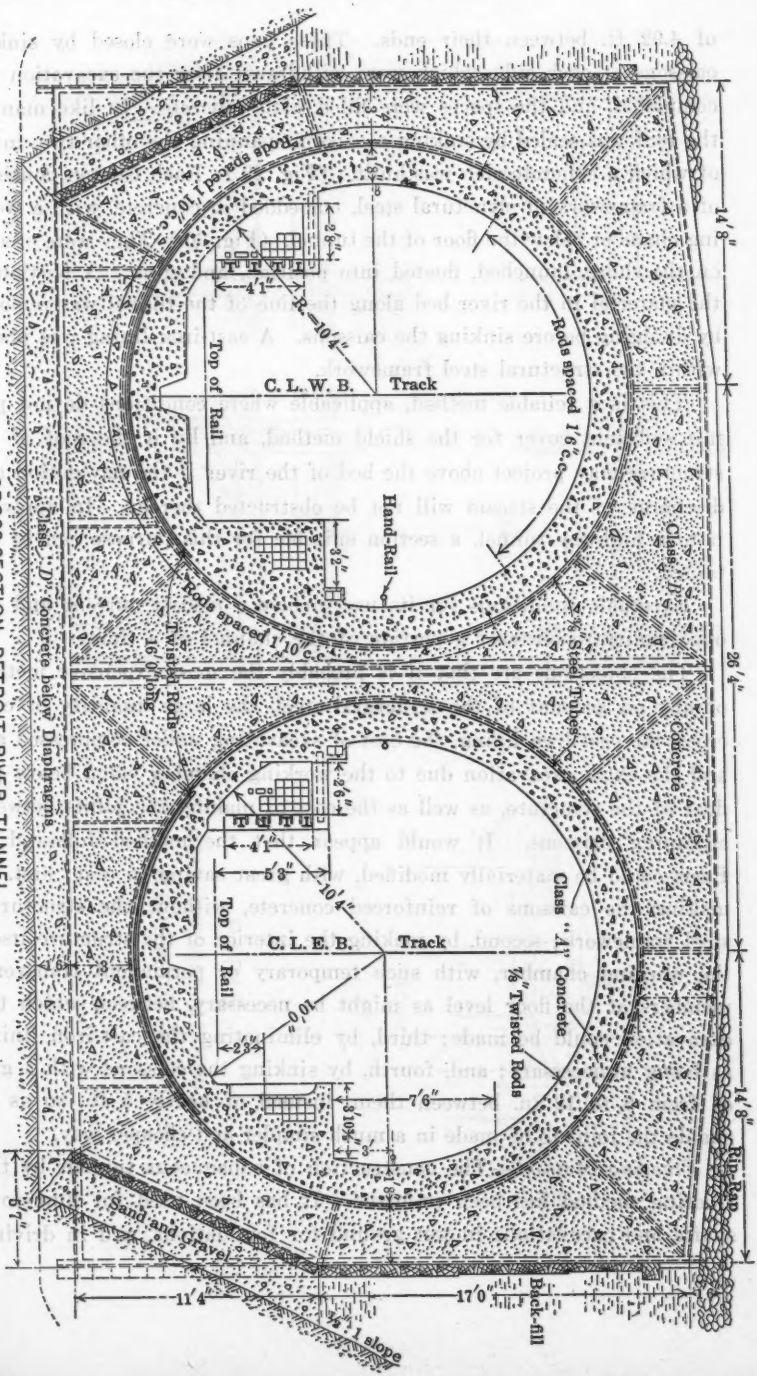
† "Les Travaux Chemin de Fer Métropolitain Municipal de Paris à la Traversée de la Seine," by L. Biette.



CROSS-SECTION, DETROIT RIVER TUNNEL

FIG. 28.

of 4.92 ft. between their ends. These gaps were closed by sinking caissons at each side, which were withdrawn after the excavation was completed, and the spaces were filled with concrete. In like manner, the roof was sealed by sinking a caisson spanning the other two, inside of which a concrete slab was built. (Fig. 29.) Each caisson consisted of a framework of structural steel, embedded in concrete, with a working chamber below the floor of the tunnel. (Fig. 30.) They were erected on the shore, launched, floated into position, and sunk. A portion of the material in the river bed along the line of the tunnel was removed by dredging before sinking the caissons. A cast-iron lining was placed within the structural steel framework.

This is a reliable method, applicable where conditions do not permit sufficient cover for the shield method, and by it the roof of the structure may project above the bed of the river if the navigation and discharge of the stream will not be obstructed thereby. In applying it to a highway tunnel, a section suitable for this purpose can be obtained.

Favorable conditions for its use involve a modest current and the opportunity to obstruct a portion of the channel at a time.

The objections are that it is probably the most expensive method of any on account of the structural steel, the large quantity of concrete, the cast-iron lining, the cost of excavating under compressed air, and the extra excavation due to the working chamber being below the floor of the structure, as well as the cost of making the joints between adjoining caissons. It would appear that the method followed at Paris could be materially modified, with great saving in cost: first, by making the caissons of reinforced concrete, without the structural-steel framework; second, by making the interior of the structure itself the working chamber, with such temporary or permanent transverse members at the floor level as might be necessary, between which the excavation could be made; third, by eliminating the cast-iron lining as being unnecessary; and, fourth, by sinking the caissons with a gap of from 6 to 12 in. between them, instead of nearly 5 ft., so as to enable the joint to be made in a much simpler and cheaper way.

Freezing Method.—The construction of subaqueous tunnels by the freezing method has been proposed. It has been used for numerous shafts and excavations in wet ground for foundations, and in driving

PARIS CAISSONS

Fig. 30.

a tunnel in wet ground in Stockholm.* A short experimental tunnel was built by this method by the Pennsylvania Railroad Company under the East River at New York, with a view to its use in the construction of the tunnel connection to the Long Island Railroad, in case the shield method should have proved unsuccessful.† It was found, however, that the rate of freezing was so slow, and the shield proved so successful, that no practical use of that method was made.

It was also used by the contractor, in an experimental way, on the East River Tunnel of the New York City subway system, at a point where he had not been able to drive the tunnel to the correct alignment and grade.‡ An attempt was made to freeze an annular space surrounding the tunnel and then to reconstruct the lining in its true position, but the method was abandoned and the tunnel was rebuilt by a different method.

The freezing method was also used on a portion of the Metropolitan Railway crossing the Seine at Paris. In building by caissons the part of the line previously referred to, it was found that some other method had to be used at the point where the line crossed under the structure and roadway of the Orleans Railway (which is built along the quay), which would not interfere with the railway operation, and the freezing method was tried.§ It was necessary to connect the last caisson in the river with the first caisson on the land, a distance of about 200 ft. This work was executed by freezing the surrounding soil by circulating a solution of calcium chlorate through pipes placed in holes bored horizontally into the soil. In clay and calcareous earth this method was fairly successful, but, when alluvial soil with boulders was reached, the boring of the holes was so difficult that the method had to be abandoned. The work was then continued by ordinary soft ground methods, with timber bracing and lagging, until a point beyond the structures of the Orleans Railway was reached. The freezing process was then resumed, using vertical tubes for the circulating medium. The connection with the caisson construction was nearly made when the water broke through the frozen material and flooded the tunnel. A bulkhead was placed across the tunnel, which was then unwatered, and the connection with the caisson was finally made by this method.

† *Transactions*, Am. Soc. C. E., Vol. LXVIII, p. 24.
‡ *Engineering Record*, December 15th, 1906.
§ *The Engineer*, July 1st, 1910.

Notwithstanding the general lack of success with this method, conditions may arise where it would be the most suitable, and it should be considered as one of the resources of the engineer.

Submerged Bridges.—Various projects for submerged tubes, or bridges, have been proposed for crossing bodies of water, the object being to avoid excessive depth and the cost of excavation. Some of these plans are very ingenious, but none has ever been carried out, although many patents on these schemes have been issued.

LINING.

The type of lining is largely dependent on the method of construction. With a circular shield, cast-iron rings with internal flanges are generally used. Cast-steel rings have been used at points where special strength was desired. Considerable thought has been devoted to the substitution of rolled, or pressed, steel segments for the cast iron, but they have been tried only in an experimental way in America. The idea has been that, for a tunnel which must have a lining of masonry, the metal lining should only be considered as a temporary sheeting to enable the permanent lining to be constructed inside thereof and as a water-proofing envelope, and that it, therefore, should be as cheap and light as possible. The tunnel under the Elbe at Hamburg was lined with structural steel with a concrete lining.

With the same object in view, several water and sewerage tunnels have been constructed with a lining of wooden segments, inside of which the concrete lining was built. The approaches to the Detroit River Tunnel were lined with wood in this way.

The Great Northern and City Railway Tunnel, London, was lined with cast iron as the shield was driven, after which the segments in the lower half of the tunnel were removed and replaced with brick masonry; the iron thus saved being used over again.

Brunel's Thames Tunnel was lined with brick masonry, as was a considerable portion of the original Hudson Tunnel, but the latter was not built with a shield.

The original Chicago River Tunnels were also of brick laid in cement, with the outer courses laid in asphalt.

The East Boston Tunnel was lined with concrete and built with a roof shield.

Concrete lining is also essential to the methods used at Detroit and in the subway tunnel under the Harlem River, New York.

Concrete blocks, in lieu of cast-iron lining, for shield-driven tunnels have been proposed and patented by John F. O'Rourke, M. Am. Soc. C. E. (Fig. 31.)*

In a favorable stratum, a subaqueous highway tunnel might be built without any artificial lining at all, but, for sanitary reasons and for ease in illumination, it is doubtful if this would be advisable. The East River Gas Tunnel, at Seventy-first Street, New York City, is about 100 ft. below the surface of the water and is only lined for a short distance in the vicinity of fissures in the rock.

As to the relative advantages of the different linings, cast iron is especially suited to shield construction, and has the advantage of being readily made water-tight, together with its ability to resist the effects of corrosion. For a highway tunnel, it has the disadvantage of being unsuited to any but a circular section. Concrete is readily adapted to a section of any shape. When used with a shield, it must have metal members embedded in it to take the thrust of the shield jacks. When in water-bearing strata under great head, it is difficult to make it entirely water-proof in itself, and it is also difficult to apply an extraneous envelope of water-proofing. A warning should also be sounded in regard to its use in strata containing acid or alkali waters, which rapidly disintegrate concrete. Such waters, though not usual, are not rare. In the first attempt to build the Detroit River Tunnel, sulphur water and sulphur gas were found in large quantities, and sulphuric acid has been encountered on other underground works, so that analyses and tests of underground waters should be made on all tunnel work.

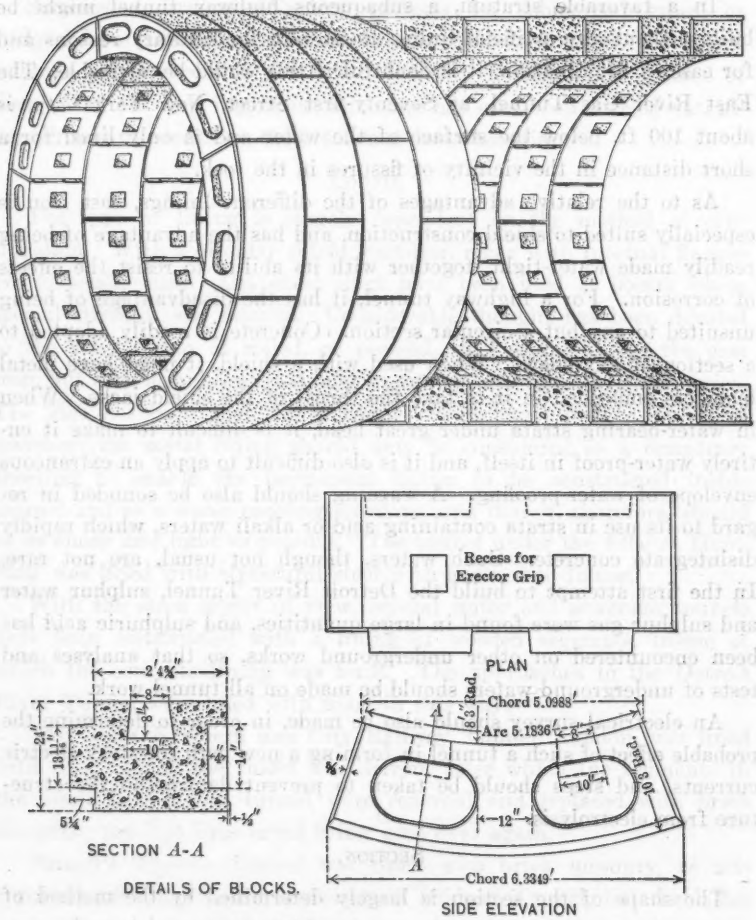
An electrical survey should also be made, in order to determine the probable effect of such a tunnel in forming a new path for stray electric currents, and steps should be taken to prevent damage to the structure from electrolysis.

Section.

The shape of the section is largely determined by the method of construction, rather than by the use to which the tunnel is to be put. Shield tunnels have generally been circular, and this section is not generally well adapted to highway purposes, a semicircular, or horseshoe section being more suitable. The Blackwall Tunnel has a 16-ft. roadway and two 3 ft. 1½-in. footwalks, and the Rotherhithe Tunnel

* *Engineering News*, November 28th, 1912.

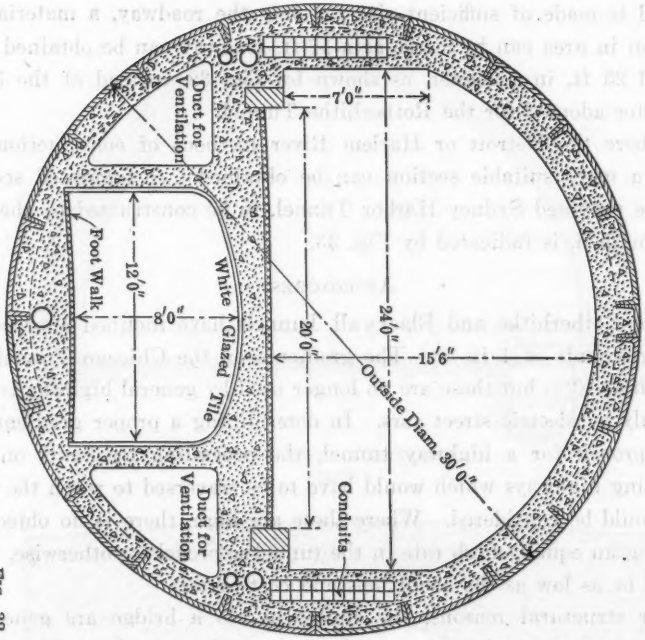
has a 16-ft. roadway and two 4 ft. 8½-in. footwalks. The section indicated in Fig. 32 is suggested as offering a more economical use of the available space, if a footwalk is essential, as it provides a 12-ft. foot-



CONCRETE TUNNEL LINING

FIG. 31.

walk and 20-ft. roadway. In tunnels more than 1 mile in length, it is doubtful if a sufficient number of persons would use the footwalk to warrant its construction, particularly where facilities are provided for crossing in electric cars in the same, or another, tunnel. If the



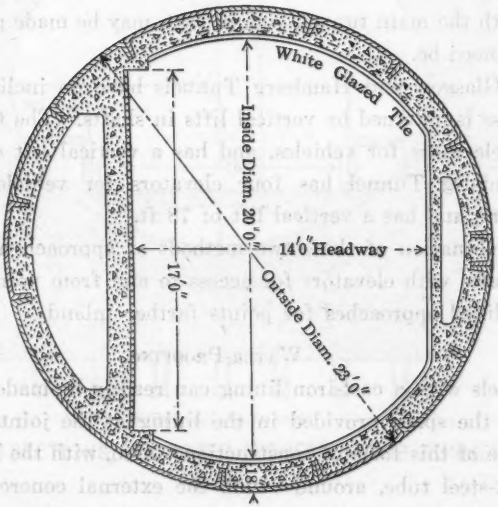


FIG. 32.—CROSS-SECTIONS, PROPOSED NEW YORK HIGHWAY TUNNEL.

tunnel is made of sufficient size for only the roadway, a material reduction in area can be made, as a 17-ft. roadway can be obtained in a tunnel 23 ft. in diameter, as shown by Fig. 32, instead of the 30-ft. diameter adopted for the Rotherhithe Tunnel.

Where the Detroit or Harlem River methods of construction are used, a more suitable section can be obtained. A suggested section for the proposed Sydney Harbor Tunnel, to be constructed by the Detroit method, is indicated by Fig. 33.

Approaches.

The Rotherhithe and Blackwall Tunnels have inclined approaches, with gradients of 1 in 36. The gradients on the Chicago Tunnel are as high as 10%, but these are no longer used by general highway traffic, but only by electric street cars. In determining a proper gradient for an approach for a highway tunnel, the prevailing gradients on the adjoining highways which would have to be traversed to reach the tunnel should be considered. Where these are high, there is no objection to using an equally high rate in the tunnel approaches; otherwise, they should be as low as the conditions and cost permit.

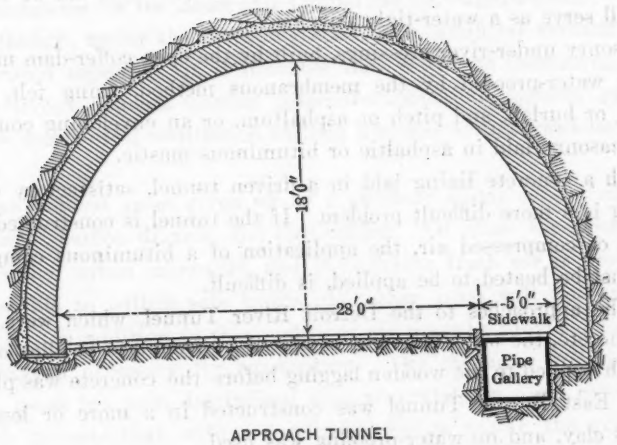
For structural reasons, the approaches to a bridge are generally made on a prolongation of the axis of the main span, but with a tunnel this is not necessary, and they may be curved or at any convenient angle with the main tunnel, and, in fact, may be made parallel with the river, if need be.

The Glasgow and Hamburg Tunnels have no inclined approaches, but access is obtained by vertical lifts in shafts. The Glasgow Tunnel has six elevators for vehicles, and has a vertical lift of about 65 ft.; the Hamburg Tunnel has four elevators for vehicles and two for passengers, and has a vertical lift of 78 ft.

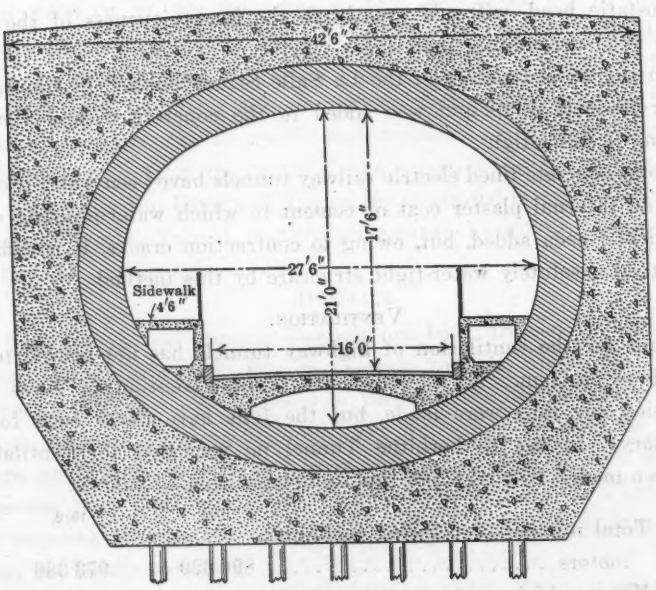
A combination of these two methods of approach may be made by using shafts with elevators for access to and from points at the shore, with inclined approaches for points farther inland.

Water-Proofing.

Tunnels with a cast-iron lining can readily be made water-tight by caulking the space provided in the lining at the joints, which is one advantage of this form of construction. Also, with the Detroit method, the sheet-steel tube, around which the external concrete is deposited, can be caulked and will keep the tunnels tight. Tunnels sunk by the



APPROACH TUNNEL
(ROCK)



SUBAQUEOUS TUNNEL

CROSS-SECTIONS, PROPOSED SYDNEY HARBOR TUNNEL

FIG. 33.

caisson process can have an inner or outer shell which can be caulked and will serve as a water-tight envelope.

Masonry under-river crossings, built by the open coffer-dam method, can be water-proofed by the membranous method, using felt, duck, canvas, or burlap, and pitch or asphaltum, or an enveloping course of brick masonry laid in asphaltic or bituminous mastic.

With a concrete lining laid in a driven tunnel, satisfactory water-proofing is a more difficult problem. If the tunnel is constructed with the aid of compressed air, the application of a bituminous compound that must be heated to be applied, is difficult.

In the approaches to the Detroit River Tunnel, which were lined with concrete, the water-proofing consisted of from 3 to 11 plies of felt and pitch applied to the wooden lagging before the concrete was placed.

The East Boston Tunnel was constructed in a more or less impervious clay, and no water-proofing was used.

The liberal use of grout at a greater pressure than that due to the hydrostatic head, will add greatly to the imperviousness of the concrete and surrounding material.

In the reconstruction of the La Salle Street Tunnel, in Chicago, a water-proofing compound was added to the concrete with a view to making it water-tight.

Some concrete-lined electric railway tunnels have been water-proofed with an internal plaster coat of cement to which water-proofing compound had been added, but, owing to contraction cracks, it is difficult to get an absolutely water-tight structure by this method.

Ventilation.

Thus far the ventilation of highway tunnels has not proved to be a serious problem. In the Blackwall Tunnel ventilation ducts and provision for fans were made, but the fans have never been found necessary. In the Rotherhithe Tunnel no provision for ventilation has been made. The traffic in this tunnel has been as follows:

	1911.	1912.
Total number of vehicles, including motors	896 629	973 336
Motor vehicles only	21 008	26 998
Maximum number of vehicles passing through the tunnel in one hour		325

Of the latter, 10 were motor-driven.

The figures for the Blackwall Tunnel are somewhat similar.

Although, under the foregoing conditions, artificial ventilation has not proved necessary, it is probable that, with the increasing use of motor-driven vehicles having internal-combustion engines, provision for the mechanical ventilation of long highway tunnels will have to be made.

The exhaust gases given off by a gasolene motor consist of carbon monoxide, carbon dioxide, and free oxygen. Of these, the most poisonous is the carbon monoxide, and if sufficient fresh air is provided to dilute this to within safe limits, the other gases will not cause any trouble. In addition to this, sufficient air must be provided to furnish the oxygen necessary for combustion. The character and quality of these gases has been determined very accurately in some recent tests* which indicate that, with a 6-cylinder, 48-h.p. motor, the quantity of air required to dilute the gases given off, within safe limits, would be about 8 000 cu. ft. per sec. when in first gear, 4 000 cu. ft. per sec., when on second gear, and 2 000 cu. ft. per sec., when on third gear. Based on these figures, it will be found that the ventilation of such a tunnel, even assuming that motor cars follow each other as closely as safety permits, can be readily accomplished. It can be effected by withdrawing air from the center of the tunnel through conduits under the floor, as in the Blackwall Tunnel, or above the clearance line, as in the East Boston Tunnel, or through separate ventilating passages, as in the Mersey Tunnel.

Drainage.

The Severn and Mersey Tunnels are both drained by letting the water leaking into them flow in separate tunnels, constructed for the purpose, from the lowest points in the main tunnels to shafts on the shore, where it is removed by pumping. In both these cases the tunnels were constructed in rock and lined with brick masonry, and the leakage was very large, but in more recent tunnels, lined with iron, steel, or concrete, the leakage is so small† that such special drainage headings are hardly necessary. In these latter tunnels the water is removed by pumping from the sumps through pipes laid along the sides of the tunnel to the shore.

*"A Comprehensive Motor Test," by Herbert Chase, *Transactions*, Soc. of Automobile Engineers, 1912, p. 40.

† Detroit Tunnel, *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 349; Hudson Tunnel, *Minutes of Proceedings*, Inst. C. E., Vol. CLXXXI, p. 169.

The art of boring large-sized holes in any direction has developed to such an extent that there is no reason why a hole cannot be bored from the sump upward through the overlying material to the bed of the river through which to discharge the drainage and thus save the long length of pipe to shore and the increased friction head.

Conclusions.

In this paper the writer has endeavored to assemble the published facts relative to all the subaqueous highway tunnels in the world, as well as of subaqueous tunnels built for other purposes, where the methods of design or construction would have an application for highway purposes. The paper, therefore, is largely a compilation, the information having been obtained from the *Transactions* of this and other engineering societies, and from the technical press. Credit for this information is generally given, but in a number of cases where the information came from various sources, the authority is not stated, and the writer wishes to take this opportunity to express his indebtedness to those who have written on this subject.

The need for improved methods of vehicular communication around harbors is manifest, and it would seem that the furnishing of this by highway tunnels has not received the attention it should. This paper, therefore, has been prepared in the hope that it will develop a discussion which will stimulate attention to tunneling for this purpose.

Commercial transportation was formerly largely conducted on the highways, and the world will shortly complete a century of railway transportation, one of the consequences of which was neglect of the highways, but the present tendency is to return to the highway for short-haul transportation, largely owing to the development of the motor vehicle for pleasure and business, which is leading to a revival in the study of road construction to meet new conditions, and highway tunnels, in many localities, are a necessary link to make this system of communication continuous.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

BY MESSRS. J. N. DODD, MORRIS KNOWLES, M. O. LEIGHTON, J. P. SNOW, ARTHUR L. MILLS, J. M. SCHREIBER, J. P. NEWELL, GARDNER S. WILLIAMS, GEORGE F. SWAIN, J. W. LEDOUX, ALBIN G. NICOLAYSEN, J. B. LIPPINCOTT, ALFRED NOBLE, M. L. BYERS, AND FREDERIC P. STEARNS.

J. N. DODD, ESQ.—The general principle involved in valuation for rate-making has been stated very clearly in the report, namely, that the primary requirement is that justice be done both to the owner of the property and to the public, and that the owner is "entitled to earn a fair return upon a fair value of the property utilized in or reasonably necessary to the service". This has been settled by the Courts, and no dissent can be taken from such ruling. On the other hand, as pointed out by the Committee, no complete or definite rule has been laid down for the determination of the fair value. Mr. Dodd.

It is becoming generally agreed that, as regards what are called public utilities, the public, as a rule, is better served by a monopoly than by competition. One gas company can manufacture and distribute gas more cheaply than six companies. The distribution by one company can be made more satisfactory, both to the consumer and to the public at large, than by six. For example, the disturbance due to tearing up the streets is far less when one company produces and distributes than when there are six.

On the other hand, the dangers of a monopoly are well realized. One of the functions of the Legislature, now usually delegated to the public service commission, is to guard against such dangers and to protect the consumer against unreasonable demands on the part of public utilities.

* Continued from April, 1914, *Proceedings*.

Mr. Dodd.

For future and for recent public service properties, the Committee favors the actual cost as the fair value. This is apparently the value to be given to the property for all time to come. For old public service properties, the Committee favors the cost of reproduction less appreciation of the identical plant at present-day prices of labor and material, mainly because it is claimed that it is impossible to determine the actual original cost of such properties.

Underlying the principle that the fair value for rate-making purposes is the "actual cost of the identical plant", is the theory that the owner of the property has a right to a fair return on the money actually invested. Such a theory has much to commend it and is widely held. Among the theories of valuation for rate-making, there is at least one other for which strong arguments can be made.

The advantages of competition are real. In ordinary business it is only when there are no restrictions, when trade is free, and when competition is unrestricted that the community is best served, that prices are lowest, that the ingenuity of manufacturers is stimulated to design the best machines, and that the capitalization of the competing concerns is kept down to a healthy figure.

A method of valuation for rate-making, which would retain for the public the advantages of monopoly and, at the same time, obtain for them the advantages of competition, would be ideal from many standpoints. It would insure to the public the advantage of the most modern machinery and the most approved methods. It would also insure to the company the full increase in the value of its properties and plant caused by the increase in the size and prosperity of the community. This latter increase is in part due to the service of the public utility corporation and, therefore, the corporation is fully as much entitled to it as the householder to the increased value of his house or lot, or the storekeeper to the increased value of location due to the improved character of the neighborhood developed around his store.

In a word, the purpose of valuation should be to restore values to a competitive basis. The rules governing the management and operation of a public utility company should differ very little from those of any other well-managed business. The community gives the company a certain monopoly. In return it has a right to all the improvements in the art and to sound business management. The city should pay prices which permit of ample allowance for depreciation and development and are commensurate with those in other lines of business.

If in ordinary business a man makes a mistake and invests in a machine which is useless or which shortly becomes obsolete, the community suffers very little. It is true that a certain amount of capital has been lost, for which, eventually, the entire community must pay,

Mr. Dodd.

but, on the other hand, the community does not continue to pay interest on the investment, nor does it continue to pay high prices for goods produced by an obsolete process.

Competitors are always ready to take advantage of all improvements and to undersell those who have made unlucky investments. Improvements are eagerly hailed, because they actually represent a gain in the wealth of the entire community, in spite of the fact that such improvements mean a serious loss to some person or group of persons.

Speaking generally, therefore, the valuation of a public utility company should be the cost to reproduce a substitute plant, such a plant as a competitor might build, not a valuation of the identical plant.

With this general plan to guide, namely, that the valuation is desired of the plant which a competitor would build to give the same service, it becomes possible to determine not necessarily all the steps of the valuation, but, in general, what is desired.

The value of the machinery should be that of the latest improved kinds to give the same service. The cost of the real estate should be its present-day cost. The value of the buildings should be their value as if built according to present-day prices of labor and material. The value of underground pipes and conduits should be the value according to present-day prices of labor and material and present types of pavements.

On the other hand, the unit prices should not be those of to-day nor of yesterday, but the average prices for a number of years past.

As regards the question of when it is satisfactory to value the identical plant and when the valuation should be of the substitute plant, the same rule of liberality should be adopted as that recommended on page 14 of the report, in regard to unused property. There is no question that a modern steam turbine is far cheaper and more efficient than a slow-speed, reciprocating engine of the type in favor, say, 10 or 15 years ago. There is no question as to the comparative advantage of a modern water-gas producer over the old type of gas retort. There is usually no question regarding the comparative suitability of three 8-in. gas mains or a single 14-in. main. When there is no question that the machines actually installed are obsolete, inefficient, and expensive, the valuation should be of a substitute plant; however, when there is room for question, it should be that of the "identical plant."

With respect to the value of real estate and of buildings, there seems to be little difference between what is recommended in the report as regards the valuation of old properties and the method advocated by the speaker for the valuation of all properties.

As to paving over conduits and pipes, it is as much an increment to the value as the development of real estate near a railroad track, an addition to the cost to reproduce the road, and a just reason for in-

Mr. Dodd.

creasing the taxes on the road. The paving adds to the cost if the competitor wishes to build; so also do the buildings restrain competitive building, in the case of a railroad. It is true that the company pays nothing for the cost of the paving, but, on the other hand, neither does the railroad pay for the buildings. Each case is a natural result of the growth of the community caused in part—sometimes in large part—by the company.

The full increase in the cost of the mains due to the paving should not be added to such cost, but only a proportion, depending on their age and estimated life. The cost of installing a competitive line is the same, regardless of the time when the paving was laid down, whether a year before or 20 years before. Therefore, if, for example, 80% of the estimated life of the main has expired at the date when the street was paved, only 20% of the added value due to the paving can be added to the capitalization of the company. In the same way, if the estimated life of the mains is 20 years, the annual depreciation which can be charged on the paving is the same percentage as on the mains, namely, 5% of the total additional cost to reproduce due to paving.

Although the report is notable for its clearness and for the many valuable contributions it has made to the science of rate-making, now in its formative stage, it appears to be open to criticism in one respect, namely, that it is difficult to determine the ground principles which underlie the proposed method of determining the cost to reproduce.

In general, it favors the actual cost of the identical plant. In the case of an old property (page 9), a deviation from this is recommended, because it is claimed to be impossible to determine the actual cost. It is difficult to accept the reason. There seems to be no insuperable difficulty in the way of determining the original cost of the labor and material of the identical units now in service.

For unused property, the report shows (page 13) that this rule is generally abandoned by the Courts, and that such property cannot be included, either at the original, or at any other cost.

As regards the present or original condition of the land (page 15), the Committee recommends that valuation should be based on the physical conditions existing at the time the property was built, but at present-day prices. In other words, it abandons wholly the idea of original cost.

When property has been donated (page 18), present-day prices should be used. Here, also, the principle is violated.

With regard to unit prices (page 30), the Committee recommends that present-day prices should be used for labor and material. The reason for this is not because of the difficulties attending the determination of original prices, but because Court decisions are in favor of present-day prices.

Mr. Dodd.

It appears, therefore, that the principle of permitting the company to earn on the actual original cost of the present property is one which the Courts have apparently refused to uphold; but, on the contrary, in all Court rulings to which reference is made in the report the present-day cost is the only one which has received their sanction (page 20).

The Courts also generally refuse to sanction unused or abandoned property as being included in the assets (page 13). Is there good reason to doubt that they will consider obsolete inefficient apparatus in the same manner, and insist on a valuation of such machinery on a basis of the service rendered?

The Courts have granted the companies the right to the full increase in the value of the real estate, caused by the increase in the wealth of the community. They have granted the companies the same right to an increase in the value of buildings. It seems fair to assume that the Supreme Court will fail to grant a similar increase in the value of the mains as affected by the pavement.

It is believed that the method offered herein of valuing a plant on a competitive basis, that is, purely present-day prices of a substitute plant, would offer fewer inconsistences and would be more permanently satisfactory.

Mr. Knowles.

MORRIS KNOWLES, M. AM. SOC. C. E.—It is not to be presumed that the Committee's report, on a question still so much in process of development, can at any time, now or after much discussion, result in the complete agreement of the membership, or in the expression of any conclusive opinion by the Society. Members will gain, however, by the free interchange of opinion, will have their ideas clarified, and may be able to agree on some few fundamental principles. The correct application will continue for a long time to appear elusive. To aid in the discussion and understanding of the report, a tabulated list of definitions, or glossary, of the important terms used would be of great help, and it is to be hoped that the Committee will add such a list before concluding the report.

The speaker's remarks relate largely to public utilities of restricted extent, with which he is more familiar, and not to railroads, because he can readily realize that the principles, at least for the present, that apply to such a utility, reaching to many different places, affecting many different peoples, and so many kinds of service, may well be different from those applying to a regulated monopoly in a narrow field.

Purpose of Valuation.—The Committee limits its report, by title and by explanation in the opening paragraphs, to the subject of "Valuation for the Purpose of Rate-Making", and states (page 5) that valuations for different purposes may not give identical results, "if the laws of the different States and certain decisions of the Courts are complied with".

Mr. Knowles.

In another paragraph (page 6), the Committee states:

"It is recognized, however, that the whole subject is in a developmental stage, and while your Committee has been guided largely by the decisions of the higher Courts and public service commissions, it recommends what seem to be sound views and desirable changes in practice, even though not wholly in accord with such decisions."

To the speaker there seems to be a certain degree of inconsistency in these statements. It is true that the subject is in a developmental stage and that the laws and decisions are constantly changing. It is common knowledge, also, that many of the recent decisions on these questions have been strongly influenced by consideration of expert testimony by engineers. May we not hope that a still larger influence in this direction will be enjoyed by this Society and its members? And, under the present conditions, would not the Committee accomplish its greatest usefulness by considering this, as it does other topics, from the point of view of sound principle, attempting to formulate true ideals, and by recommending practices which approximate these ideals as closely as existing laws and decisions permit? When authorities differ so widely, this would seem to be much more preferable than merely recognizing existing conditions and practices, and attempting to formulate ideals from them.

President Wilson has aptly stated "the day of accommodation, of concession, and of common understanding is, of necessity, a day of achievement". We are rapidly coming to the common understanding that fair return means equity, that it has all the force of its literal significance, alike to server and to user, *viz.*, an equality in value between the wealth, labor, and effort devoted by the owner to the public use, and the money returned to him by the public in rates. When this has finally been thoroughly established, a consideration of the matter in the light of principle will lead, the speaker believes, to the conclusion that valuations for all purposes, under complete and comprehensive regulation, should be identical.

It is true that no useful purpose would be served now by attempting to insist under the present laws that valuations for taxation be identical with other valuations, but the reason for this is that the problem of valuation for taxation is not a problem in valuation at all, but one in taxation. The method of valuation for taxation is fixed by the tax laws, and not by any consideration of the true meaning of valuation. The speaker believes that when an ideal system of taxation has been worked out, if it is based on property valuation at all, and requires valuation of public utilities for taxation, such valuations will be identical with those for purchase, capitalization, and rate-making. Until that time, the varying requirements of taxation laws cannot be adduced as throwing any light on the subject of valuation.

Mr. Knowles.

The following statement is made, on page 8 of the report:

"As the future earning capacities of such properties under rate regulation by commissions will to a large extent depend upon rates to be established as a result of valuations of the properties, it is clearly illogical to base the valuations on present or past rates. Such valuation would be reasoning in a circle."

If such be the case, and if in the future the purchaser will be held down, and if he cannot earn on a different or greater value than that fixed by public regulation for rate-making, where will be the incentive to pay more for the property; what will keep alive the spirit of gambling in the future?

If it is agreed that a fair return is to be permitted on everything that the owner of a public utility has devoted to the public service, then the value for rate-making purposes will be the total actual reasonable investment, including all preliminary and development expenses and every sacrifice of time and labor, as well as of money. If returns on this value are limited to the market rate of borrowed capital under the given conditions of risk, then the value of the property for purchase would be that return capitalized at the same market rate of interest, or a value identical with that for rate-making purposes; and, if capitalization is to be controlled, so as to represent the actual investment, either of the original owner or of the purchaser, then the valuation for capitalization will be identical with those for rate-making and purchase.

The speaker then, while recognizing the laudable desire of the Committee to limit its report to one subject at a time, suggests that it is unwise to place on record, even by implication, that, either for present legal reasons or otherwise, valuations for different purposes will necessarily give different results. It would seem as if the Committee could be of more service by insisting throughout on the principles involved, instead of compromising, as in the statement first quoted above, with existing laws and decisions of Courts.

Present Conditions to Govern.—The report recommends: "the method of valuing the substantially identical property" according to "original conditions"; but goes on to say "valuations should be based upon the physical conditions at the time the various portions were built, but at the prices prevailing at or near the time of the valuation." This is manifestly an inconsistency, and an unnecessary straddle.

Let us analyze the attempts on the desire to do justice to the owner and rate-payer: It is generally recognized, as so ably stated by the Committee, that original cost, to include all proper items, and elements, and percentages, will give the desired result, if obtainable. It is rare that this can be determined, and this has led to the method—born of necessity—of estimating the cost-of-reproduction-new; determining

Mr. Knowles.

all factors as of the time of valuation, with normal prices for the preceding few years; but this should never be considered an end in itself, but only a means of throwing light on the probable original cost; and, if this is kept in mind, there will be no excuse for confusion arising from doing partly one thing and partly another. Granted that full historical and book cost may be difficult, even impossible of complete determination, and that, better than present-day-cost-of-reproduction is the cost-of-reproduction-with-original-conditions; the speaker submits that if "original conditions" can be determined, or even approximated, it is also true that prices at the time of construction can be even more accurately found, as these are frequently of record in the engineering and business periodicals, and in published reports and contracts of the time of construction. By using these we shall thus have harmony and consistency of thought and purpose.

Depreciation.—The Committee's statement on this subject is perhaps the most novel presentation in the report, and will arouse the greatest discussion. Time has not permitted an adequate analysis of the supplemental statement on this subject, but just a word may not be amiss. We have heard a great deal of the equity of charging rates upon 100% of cost new, on the basis that the service is kept up, that it is of full worth and therefore should be paid for accordingly, no matter what is done with the depreciation fund. This, we are told, is the concern of the stockholders. Now, much of the confusion and disappointment in the past have come from the endeavor to secure from these same stockholders the full repayment to keep up plant and service; and these stockholders are too frequently the "ubiquitous widows and orphans", who have acquired their stock from original owners who "got out from under" after drawing dividends at the expense of the depreciation fund.

Perhaps it would help us understand the position, so ably presented by John W. Alvord, M. Am. Soc. C. E.,* when he says the value for calculating rate of return depends on whether the fund has been kept intact, if we would remember not only that this fund, made up by annual payments by whatever system, is due the owners, that is, shall be paid in each year by the rate-payer, but also that the owner must preserve this fund intact for the purposes for which it was created. That is, it is a trust fund, and the owner has all the solemn duty of a trustee to preserve the fund for use in keeping up the property for the user who has paid into this fund.

It may even be true, in some cases of stagnant property and in order that refunding of bonds at maturity may be possible, that some small payment to a sinking fund as well may be necessary. This has been hinted by the Committee on page 7, when it says:

Transactions, Am. Soc C. E., Vol. LXXVII, p. 788.

Mr. Knowles.

"It is not enough * * * that the borrower should pay interest on the money loaned, but he must also pay the principal to cancel his indebtedness."

TABLE 19.—STATEMENT OF ENGINEERING COST ON CONSTRUCTION, BETWEEN APRIL 1ST, 1904, AND JANUARY 31ST, 1910, ON PITTSBURGH FILTRATION WORKS.

Contracts.	Final estimates.	Engineering Cost.	
		Total.	Percentage of final estimates.
1. Slow sand filters, basins and appurtenances	$3 359 161.49	$332 854.65	9.91
2. Filtered water reservoir and appurtenances	415 245.28	46 398.07	11.18
3. River crossing and connections at Brilliant	266 474.36	27 944.26	10.47
4. Centrifugal pumps, engines, generators and appurtenances, at Ross pumping station	92 956.30	4 385.76	4.72
5. Boilers, economizers, piping and appurtenances at Ross pumping station	68 403.53	2 676.59	3.94
6. Sand washers, electric machinery and auxiliary equipment for Ross pumping station	122 568.21	11 804.29	9.60
7. Ross pumping station	356 580.69	41 324.24	12.58
8. River wall, intakes and connections and grading, pumping station and machinery foundations	208 318.92	26 933.76	12.94
9. Pumping engines, boilers and appurtenances at Brilliant pump station	218 028.37	9 767.27	4.48
10. Pipe line and appurtenances, Highland Reservoir No. 2 to South Side	555 250.76	34 877.71	6.28
	$5 662 987.91	$538 966.60	9.52

TABLE 20.—FINAL DISTRIBUTION OF CONTRACTOR'S COSTS BY BUREAU OF FILTRATION, ON PITTSBURGH FILTRATION WORKS.

	Contract No. 1. Slow Sand Filters and Appurtenances.		Contract No. 2. Filtered Water Reservoir and Appurtenances.		Contract No. 3. River Crossing and Connections at Brilliant.	
	Amount.	Percentage of total.	Amount.	Percentage of total.	Amount.	Percentage of total.
Materials and sub-contract items	$1 733 378	47.2	$165 758	35.3	$105 567	35.0
General supplies	127 402	3.4	16 087	3.4	10 327	3.4
Plant	275 249	7.5	34 766	7.4	22 318	7.4
Pay roll	1 164 613	31.8	206 113	43.9	133 572	44.3
General expense	254 672	6.9	32 156	6.8	20 644	6.8
Interest and general overhead charge	115 250	3.2	14 570	3.2	9 342	3.1
	$3 670 564	100.0	$469 450	100.0	$301 770	100.0

Engineering and General Expenses.—To those who have viewed with wonder the generally accepted basis for costs of engineering services of 5% and 6%, it is gratifying to note the results of the Commit-

Mr. Knowles.

tee's inquiries into such costs on great and important water-works and transit systems, revealing amounts of 8 and 10 per cent. The speaker is glad to add one more set from the records of the Pittsburgh Filtration Works, from 1904 to 1910, inclusive, in Tables 19 and 20.

Extra Capacity.—The position of the Committee in regard to valuing all the property, including reasonable allowances for increased size, capacity, and availability for the future, cannot be too earnestly commended. No one with judicious foresight should be held down to designing works for the present only. Reservoirs, pipe sizes, filters, buildings, pumps, all need to be planned in varying degrees for the probable needs of a number of years. This is but ordinary good business judgment, and the sooner we can get the Courts to recognize this principle the better for all.

Mr. Leighton.

M. O. LEIGHTON, M. AM. SOC. C. E. (by letter).—The writer will participate in this interesting discussion only to the extent of calling attention to an interesting Court decision with reference to a much disputed point in the determination of "replacement value".

Mr. Allen Hazen, in his discussion of this report, makes the following statement:

"* * * in estimating the cost of reproduction of a water-works plant, the cost of cutting through the paving of the street over it, and replacing such pavement after laying the pipe, is unquestionably a part of the cost of reproduction, and must be included in any true estimate of it. The Committee, however, would exclude all that part of the cost which relates to paving laid after the pipe was placed. The writer is unable to see that the question of whether the pipe or the paving was laid first has anything to do with the cost of the reproduction of the property as it now stands, or with its value. It would cost just as much to replace the pipe in one case as in the other. The value of the property, as measured by its capacity for useful service, is identical in both cases."

On March 24th, 1914, the Court of Appeals of the State of New York, handed down an opinion in the case of the Kings County Lighting Company *v.* the Members constituting the Public Service Commission of the State of New York for the First District. Among the questions certified for decision were the following:

"Was the relator entitled, upon the facts shown in the record, to have the cost of reproduction of paving now in the streets but not in place at the time the mains were laid, allowed for in ascertaining the value of its property used in the public service?"

"Was the relator entitled, upon the facts shown in the record, to have the cost of reproduction of paving now in the streets but not in place at the time the mains were laid, allowed for in ascertaining the capital actually expended?"

Mr. Leighton.

With reference to the two foregoing questions, the Court said:

"In determining the cost of reproduction, the Commission allowed $12 717 as the cost of restoring the pavement as it existed when the mains and service pipes were laid in the streets. The relator claimed an allowance of at least $200 000 for the cost of restoring pavements subsequently laid, on the theory that that cost would have to be incurred if the mains were to be laid to-day. But the new pavement in fact added nothing to the property of the relator. Its mains were as serviceable and intrinsically as valuable before as after the new pavements were laid. The controlling considerations under the preceding point also determine this. The rights of the public are not to be ignored. The question has a double aspect. What will be fair to the public as well as to the relator? (Smyth *v.* Ames, *supra*). Should the public pay more for gas simply because improved pavements have been laid at public expense? It is no answer to say that the new expensive pavements suggest improved conditions which, though adding to the value of the plant, will not, by reason of the greater consumption, add to the expense per thousand feet of the gas consumed. The public are entitled to the benefit of the improved conditions, if thereby the relator is enabled to supply gas at a less rate. The relator is entitled to a fair return on its investment, not on improvements made at public expense. It is said that the mains will have to be relaid. So will the new pavements, and much oftener. Both might possibly be relaid at the same time. The case is not at all parallel to the so-called unearned increment of land. That the company owns. It does not own the pavements, and the laying of them does not add to its investment or increase the cost to it of producing gas. The cost of reproduction less accrued depreciation rule seems to be the one generally employed in rate cases. But it is merely a rule of convenience, and must be applied with reason. On the one hand, it should not be so applied as to deprive the corporation of a fair return at all times on the reasonable, proper, and necessary investment made by it to serve the public, and, on the other hand, it should not be so applied as to give the corporation a return on improvements made at public expense which in no way increase the cost to it of performing that service."

Mr. Snow.

J. P. Snow, M. Am. Soc. C. E.—The following has been suggested by the printed discussions of the report which have so far been issued.

In formulating its report, the Committee assumed certain fundamental principles to be axiomatic which several critics of the report have considered open to discussion. An explanation of a few of these will render the discussion clearer.

First.—It is claimed by some that valuations cannot be used in fixing rates for public utilities, especially for steam railroads. It seems idle to make this claim, in view of the facts that an Act of Congress provides for the valuation of railroads, and the Interstate Commerce Commission and its engineers state that valuations are an important factor in fixing just rates, and must be ascertained at whatever cost for their information and use. The railroads of the country are preparing

Mr. Snow.

to make these valuations, and the Government engineers are organizing their forces to check the work. Where, then, is the force in the argument that these valuations cannot be used, and that the Committee should not have considered valuation for rate-making purposes in its report.

Second.—Several of those who have discussed the report claim that, because an item of property is rendering efficient service, although it is confessedly near the end of its life, it should be scheduled as having value new. This idea rests on the theory that rates should be based on the value of the service to the consumer, instead of on the cost of the service to the producer. Although aware that in the last analysis the law of supply and demand rests on a balance of these two theories, the Committee is firmly of the opinion that the value of service to the consumer cannot be used as the basis for computing rates in terms of money. Property must be kept in a state of full efficiency; else rates cannot be collected at all. When an item reaches the stage where its efficiency is practically impaired, it must be replaced and either scrapped or relegated to other parts of the service where less efficiency suffices. It follows that continued efficiency cannot be considered as a reason for holding an item in the schedule at value new throughout its term of life.

Third.—Protection of the investment seems to be another stumbling block with many who have discussed this question. The aim of the Committee has been to protect the owner in the legitimate, proper value of his property, based on present prices and original conditions so far as they have largely controlled the cost and are definitely known. If investment *per se* is to be considered, shall it be the original cost of an old property, or the cost to the present owners? Is the cost entirely legitimate? Has there been appreciation of value in some part of the holding? Has some part of the property been acquired by gift? These and many other questions render a full dependence on investment cost impossible and unjust—unjust sometimes to the consumer and sometimes to the owner. Justice seems to require that original conditions be considered as above, especially as regards the improvements on real estate, paving over pipes already laid, etc., because the legitimate, proper cost, so far as ascertainable with certainty, plus appreciation and minus depreciation, is the value. Higher present unit prices are an item of appreciation; and lower, of depreciation. Paving over pipes is a factor of added cost when replacement occurs, plainly chargeable at that time to capital as betterment, under the Interstate rules for railroad accounting.

Although the consideration of original conditions to any extent seems to hark back to that of investment, it does so only in so far as strict justice, to the owner on the one hand and to the rate-payer on the other, demands.

Mr. Snow.

It must not be supposed that hard and fast rules can be adopted for solving the problem of valuation for rate-making purposes, and can be extended to cover abnormal cases. Tolls on the Panama or New York Canals cannot be fixed by the Committee rules any more than can the price of diamonds from the Kimberly Mines. The application of any rules on the subject must be tempered by common sense, and this necessity has been kept in mind at all times by the Committee.

Referring to the discussion by Messrs. George F. Swain, D. W. Lum, and others: The word "rate", as used by the Committee, should be assumed to mean the gross income from the physical property which is valued; and does not go into the intricacies of a schedule of individual rates like a railroad tariff sheet.

The difference between using interest return on value new plus a sinking-fund allowance, as advocated by George F. Swain, Past-President, Am. Soc. C. E., and the Committee's recommendation of interest on depreciated value plus a depreciation allowance, depending on the life of an item and its age, lies more in the bookkeeping than in the amount of money involved.

Mr. Swain's is the easier method for the engineer, in that only the value new of the item and its term of life are needed, while the other method requires in addition the age of the item. The objections to his method are serious, however, and apparently very practical. The speaker begs leave to differ with him by thinking that the sinking-fund method is the ideal, impractical one and the Committee's the practical method. With the sinking fund the annual payments with their interest must be kept intact as funds which the stockholders must not profit from, else there will not be sufficient in the fund when the time for replacement comes. Now, in railroad practice, such funds can be used much more profitably in betterments to the property in general, where, of course, they will earn the higher rate assumed as possible by the rest of the property, than if loaned as ordinary investments at interest. This, then, would be the obvious and proper way in which to invest them; but, if so invested, the company must keep their earnings separate, except as used for straight replacements, rigorously withholding all earnings from betterments created by such funds from dividends, else the replacement fund will not be kept inviolate.

It is assumed that Mr. Swain would allow the return from value new as available for dividends, while the sinking-fund accumulation would provide at the proper time for replacements. If these annual sinking-fund allowances are used for additions and betterments, as is shown above to be advisable, can he separate these "fund items", as they might be called, so that the interest allowed on their value new would not be paid as dividends, instead of being held as they should be to build up the replacement fund?

Mr. Snow.

Another objection is the repeated findings of the Supreme Court that an item cannot be held as of the same value as when new after it has passed an appreciable portion of its life term. If we may ignore the Courts, as has been suggested, many things not now thought advisable may be done; but, when these findings appear to be equitable and good law to so many of us, it is a question if it is not best to conform to them with good grace.

The Courts also set forth valid objections to a utility company accumulating a fund of any kind, but hold rather that it should pay as it goes, collecting sufficient revenue to do so.

By the replacement method, as advocated by Mr. Lum, the result is that the customers after the replacement have to pay the bill, rather than those who have enjoyed the use of the item while it was in service. This is seen more plainly in the case of a large item, like a water-works reservoir or a terminal railway station, than in the case of railroad ties, although the principle is theoretically the same.

To show that the method of the Committee in allowing return on remaining value is just and covers the exact new capital put into the property, Table 21 is submitted. Assume a business consisting of ten items of equal value, with life terms of 10 years, and that one item is installed each consecutive year until the ten are in use. The value new is represented by 100, and depreciation is computed by the equal-annual-payment method, recommended by the Committee, on a 7% basis.

The remaining value of each item at the end of each year is shown in the body of the table, and Column 12 shows that after one cycle, *i. e.*, 10 years, the total of the remaining values remains constant at 605.39. Column 14 shows that this sum also represents the total new capital that has been put into the property, assuming that the regular allowances for depreciation each year have been used toward establishing the new item due the following year. Interest on this sum (605.39) plus depreciation, as recommended by the Committee, is manifestly the proper measure of the return from these items of property to use when fixing rates.

If the straight-line method of depreciation had been used, the resulting total remaining value after a life cycle had passed would have been 550.00, and this figure would represent the amount of new capital needed under the conditions named above.

The reason for the smaller capital investment when depreciation allowances are computed by the straight-line method is, of course, that the early payments are large and consequently a greater return accrues to the owner's benefit than happens under the equal-annual-payment method. The final outcome at the end of the life cycle is the same if interest is fully allowed for in both cases.

Mr. Snow.

TABLE 21.—LIFE HISTORY OF A PROPERTY CONSISTING OF TEN EQUAL ITEMS WITH LIFE OF 10 YEARS. ASSUMING THAT ONE ITEM IS ADDED EACH CONSECUTIVE YEAR.

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)

Mr. Snow.

Another objection is the repeated findings of the Supreme Court that an item cannot be held as of the same value as when new after it has passed an appreciable portion of its life term. If we may ignore the Courts, as has been suggested, many things not now thought advisable may be done; but, when these findings appear to be equitable and good law to so many of us, it is a question if it is not best to conform to them with good grace.

The Courts also set forth valid objections to a utility company accumulating a fund of any kind, but hold rather that it should pay as it goes, collecting sufficient revenue to do so.

By the replacement method, as advocated by Mr. Lum, the result is that the customers after the replacement have to pay the bill, rather than those who have enjoyed the use of the item while it was in service. This is seen more plainly in the case of a large item, like a water-works reservoir or a terminal railway station, than in the case of railroad ties, although the principle is theoretically the same.

To show that the method of the Committee in allowing return on remaining value is just and covers the exact new capital put into the property, Table 21 is submitted. Assume a business consisting of ten items of equal value, with life terms of 10 years, and that one item is installed each consecutive year until the ten are in use. The value new is represented by 100, and depreciation is computed by the equal-annual-payment method, recommended by the Committee, on a 7% basis.

The remaining value of each item at the end of each year is shown in the body of the table, and Column 12 shows that after one cycle, *i. e.*, 10 years, the total of the remaining values remains constant at 605.39. Column 14 shows that this sum also represents the total new capital that has been put into the property, assuming that the regular allowances for depreciation each year have been used toward establishing the new item due the following year. Interest on this sum (605.39) plus depreciation, as recommended by the Committee, is manifestly the proper measure of the return from these items of property to use when fixing rates.

If the straight-line method of depreciation had been used, the resulting total remaining value after a life cycle had passed would have been 550.00, and this figure would represent the amount of new capital needed under the conditions named above.

The reason for the smaller capital investment when depreciation allowances are computed by the straight-line method is, of course, that the early payments are large and consequently a greater return accrues to the owner's benefit than happens under the equal-annual-payment method. The final outcome at the end of the life cycle is the same if interest is fully allowed for in both cases.

Mr. Snow.

Mr. Snow.

To show the advantage of the equal-annual-payment method over the straight-line method when rates are to be determined, the diagram and table, Fig. 7, has been prepared. The depreciation by the straight line is, of course, 10 each year. This, added to the interest on the remaining value each year, is shown graphically at the left of the

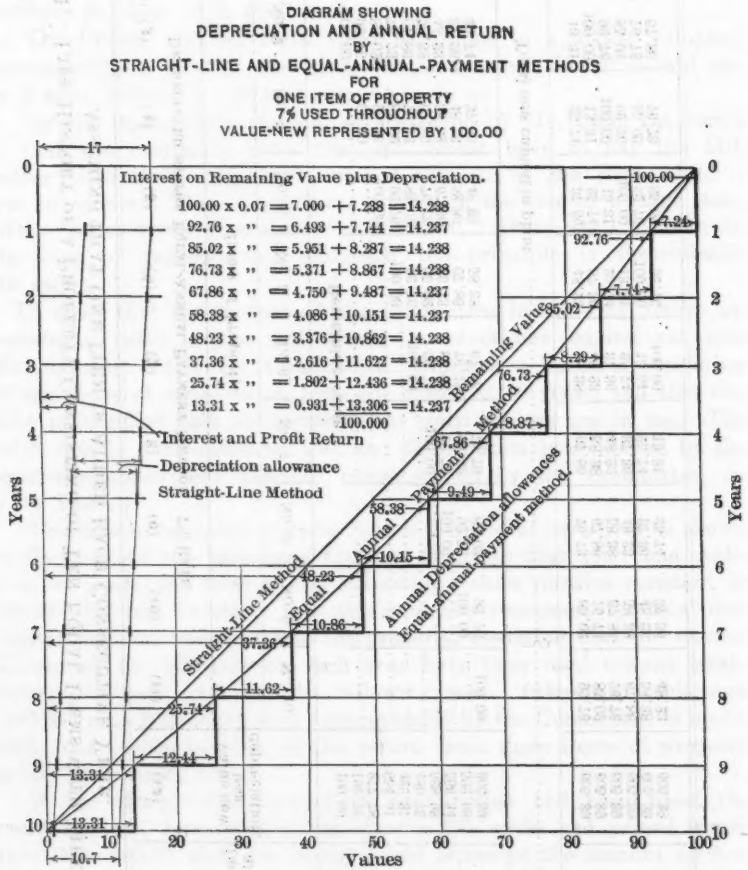

FIG. 7.

diagram. The total return will be seen to vary from 17 at the end of the first year to 10.7 at the end of the cycle, averaging 13.85. The similar features by the other method are shown by the table on Fig. 7, and will be seen to be constant for each year at a value of 14.24. It will be appreciated by all that level rates year by year are to be preferred to those which vary.

Mr. Snow.

The interest and profit returns on remaining value, varying from 100 the first year to 605.39 at the tenth, by Column 12 of Table 21 is the proper amount to distribute as dividends; and the amounts in Column 13, of course, should be put back into the property. The figures of this column apply to the beginning of the year at which they are placed, or to the end of the preceding year, and, to obtain total return, must be added to the interest and profit return on the capital in the plant during the preceding year. If this is done it will be seen that the rates or gross income should be 14.238 at the end of the first year and direct multiples of this for other years up to the tenth; after which it remains constant at 142.377, or ten times the first return, as it should, as there are then ten items of property involved to one item at the beginning. The sum of Columns 13 and 14 at the beginning of the tenth year is 1 000, equalling ten full items, as it should.

If items of varying value or of irregular periods of installation had been assumed, the calculation would have been more complicated and the result not so clearly shown, but the principle would have been the same, and the equitable division between dividend and depreciation monies as clearly set forth.

If the sinking-fund method is used, the figures of Column 13 will be multiples of the first figure, provided the funds are invested outside, as a regular sinking fund should be. If put back into the property, the column becomes quite complicated, and the proper return available for dividends still more so. Under this last assumption, however, the actual amounts of new capital put in and the yearly returns will be the same as with the equal-annual-payment method shown, but, if the percentage of value new is distributed for dividends, the depreciation funds will suffer.

If, under the sinking-fund method, each item is paid for with new capital and the depreciation fund is invested outside, the new capital at the tenth year will be 1 000, the annual percentage on which is 70, and Column 13 will consist of multiples of 7.2377, which is its first term, the tenth being 72.377, as by the other method. This shows that the difference between these methods is one of bookkeeping, and the objection to the sinking-fund method is that a separate outside fund must be maintained or great risk run of distributing too much in dividends, thereby robbing the depreciation fund.

Considering the replacement method advocated by Mr. Lum, Column 13 would consist of zeros to the end of the tenth year. From the eleventh year onward the figures would be 100. The new capital would increase by 100 each year for 10 years, and the annual returns would be 7 for the first year and multiples thereafter to the tenth year. Hence the public should pay for the ninth year 63, for the tenth year 70, and for the eleventh year 170. This would necessitate

Mr. Snow. a great jump in the rates or a cut in the dividends. For ordinary railroad operation, renewals can be arranged so as to be fairly uniform from year to year, but when a great terminal is rebuilt, the above jolt occurs and, as it is difficult to raise rates, dividends must suffer, as local instances show.

Careful study of the tables in the report and the various ones since submitted by the Committee will show the entire equity of the equal-annual-payment method and its certainty to protect the company owning the property considered.

Mr. Mills. ARTHUR L. MILLS, M. AM. SOC. C. E. (by letter).—When the real estate of a company is of comparatively small value, the treatment of appreciation is of no great importance, as earnings cannot be provided by regulation with any degree of precision; but when the value is large, it may become a serious problem.

The value of the real estate of the four principal railroad lines to Chicago, the New York Central, Pennsylvania, Erie, and Baltimore and Ohio, probably exceeds $1 500 000 000. The appreciation of this real estate has averaged at least 5% per year in the last 20 years. If this appreciation is, in the future, to be considered as part of the income, it means that the estimated income will be greater than the actual income by $75 000 000 per year; whereas the estimated increase in income for all the roads in this territory by the 5% advance in rates which these roads desire, is only about $40 000 000.

The U. S. Supreme Court has decided that the cost of reproduction or present value of the property must include the value of the real estate at the time of the valuation.

The New York Public Service Commission in the First District includes in the probable income the estimated appreciation of the real estate; but the Appellate Division of the Supreme Court of the State of New York, in a decision rendered in May, 1913, refused to adopt this view. The inclination of the Interstate Commerce Commission at that time is indicated in the decision in the Western Rate Case. Commissioner Lane said on this subject:

"Whatever the true economic or legal view may be as to the right of a carrier to consider the increase in value of its land as a part of the value upon which it is entitled to a reasonable return, such increase in value does not of itself establish the right of a carrier to increase rates upon a given service. Certainly if the Supreme Court may decline to lay down the absolute rule that 'in every case failure to produce some profit to those who have invested their money in the building of a road is conclusive that the tariff is unjust and unreasonable', *Regan v. Farmers' Loan & Trust Co.*, 154 U. S., 412, it is a conservative statement of the law to hold that a railroad may not increase the rates upon a number of commodities solely because its real estate has arisen in value."

Mr. Mills.

"While it is evident, therefore, that each case must be decided upon the facts peculiar to it, the Commission believes it proper in this case to follow the general rule, as stated by Judge Hough of the United States Circuit Court (Consolidated Gas Co. *v.* City of New York, 157 Fed. Rep., 855):

"'Upon reason, it seems clear that in solving this equation the plus and minus quantities should be equally considered, and appreciation and depreciation treated alike. Nor can I conceive of a case to which this procedure is more appropriate than the one at bar.'

"Thus, land has been taken at its fair value and not at its original cost, and the annual appreciation of land has been treated as a profit. By this method, all property is treated absolutely alike, as Judge Hough suggests. No difference is made, except that as depreciation represents a decrease in assets, it is placed as a *debit* against operation, while appreciation is placed as a *credit*, because it is an increase in assets. Land has sometimes been treated like other property only to a degree; that is, each class has been appraised at its present worth or value. That has been done in this case. But if property has been taken at its *depreciated* value where it has depreciated, an entry must regularly be made in estimated operating expenses equal to the average annual depreciation. Conversely, if land, or any other property which genuinely appreciates in value, is to be taken at its *appreciated* value, then an entry must be made in the estimated receipts equal to the average annual appreciation. Unless this is done, it is obvious that the consumer will be burdened with all the estimated decreases in assets but not credited with the increases in assets. If the principle laid down by the court is to be followed in part, it should be followed in whole.

"It is suggested that the annual increase in the value of land which is treated as income is not actually received. Increase in the value of unoccupied land is not realized until sold or put to use, but it is real, nevertheless, although payment may be deferred. Likewise, payments to the depreciation fund are not actually expended; yet they have been considered legitimate charges in practically every case. Furthermore, the *annual* increment is no more indefinite than the *total* increment—the present value. But if the present value can be determined, it is possible to determine past *annual* appreciation with positive accuracy, for it is only a simple mathematical calculation. It is also probably as easy to estimate increases in the near future as it is to estimate what obsolescence, which is a form of depreciation, there will be in the future.

"Indeed, the problem of handling appreciation is much simpler than depreciation. If the property is growing more valuable, the investor need not worry; and if the state recognizes his right to earn a fair return upon the increase, he is fully protected. It is not necessary that the increase be represented by stocks or bonds, for if the earning power is there, he will receive a return thereon, regardless of the amount of securities. In fact, the existence of an increase which is not represented by securities is an element of safety, a reserve fund of a valuable kind.

Mr. Mills.

"There is a further similarity. The exact amount of depreciation and the annual rate are not definitely known until the piece of property is actually replaced or has become useless. The total appreciation and the average annual rate are not known until the land is sold, but when it has been disposed of (and plants are continually being removed and the land sold), they become absolute certainties. Why should these matters be considered less definite when applied to land than when applied to the buildings thereon? The depreciation of the buildings is a charge against operation; why should not the appreciation of land be a credit?"

Mr. Lane's statement, "it is a conservative statement of the law to hold that a railroad may not increase the rates on certain commodities solely because its real estate has risen in value", may be fair as an abstract proposition; but it does not follow that an advance in rates should be denied because it would permit a return on the appreciated value of the real estate. The U. S. Supreme Court in many cases has laid down the general principle that the owner is entitled to fair return on the fair value of his property, regardless of cost, provided the rates are reasonable. It would probably be considered against public policy to allow railroads to raise their rates simply for the purpose of paying excessive dividends, even if such an income would be no more than a fair return on the value of their property. It does not follow that the cost of reproduction or present value will necessarily be the controlling factor in rate regulation. The Supreme Court has decided that the original cost, cost of improvements, and the value of the stocks and bonds, must also be considered, and that, regardless of everything, the rates must be reasonable.

Where a railroad needs more money to meet its expenses and also the demands of an increasing tonnage, and to keep up its dividend rate which is not excessive, however, it appears equitable to permit an increase in rates, provided the proposed rates are reasonable and the anticipated income is not more than a fair return on the fair value of the property, regardless of the original cost of the real estate.

Appreciation and depreciation are separate and distinct processes, and each should be considered on its own merits independently of the other and by reason of the effect it has on the present value. It is found necessary to provide from the earnings the cost of the depreciation of the structure, due to wear and tear, etc., for the reason that it is a necessary expense and one that cannot be neglected without damage to the property; but this in itself is not a valid reason for considering appreciation as an income.

Appreciation is not an actual receipt, and is of no assistance to the railroad in meeting its disbursements. To the extent, therefore, that estimated receipts include estimated appreciation, they will, for all practical purposes, be fictitious. Moreover, because real estate has appreciated at a certain rate in a term of years, it does not follow that

Mr. Mills.

the appreciation will continue at that or any other rate. The value of real estate frequently remains unchanged for a long time and then increases rapidly for a few years. Any estimate of the future appreciation of real estate is speculative, as many purchasers of that class of property know to their sorrow.

Appreciation of real estate is available as income only when the land is sold, and, as a railroad is rarely able to sell its real estate, the stockholders cannot ever expect to realize any income from real estate appreciation.

The real estate of a railroad is different from that of most other corporations. In rare cases only is a road able to dispose of even a part of its land. The demands of a constantly increasing business make it necessary to purchase additional land. It is doubtful if the actual value of the real estate is given any consideration by investors in railway securities. To suppose that the real estate of a railroad may be sold, is to pre-suppose its bankruptcy and abandonment.

Appreciation of real estate differs in character from the depreciation of the physical property due to wear and tear, obsolescence, etc.; it resembles depreciation due to a decline in the prices of rails, equipment, etc., from the prices paid at the time of their purchase, but this kind of depreciation is neglected in a valuation.

Mr. Lane says that unless appreciation is considered a part of the income "it is obvious that the consumer will be burdened with all the estimated decrease in assets but not credited with the increases in assets". The consumer is not burdened with depreciation because it is a decrease in the assets, but because it is a part of the expense of operation. It is something that requires money, and unless appreciation can provide money it does not seem equitable to use it as an offset to depreciation or for any other reason.

One is almost forced to the conclusion that the idea of including appreciation as a part of income did not originate from considerations of equity, but from a desire to find some way to offset the effect of the continuing appreciation of real estate which, in time, will increase the physical values of railroads so that a fair return thereon will permit excessive dividends, and to prevent future reductions of the rates.

It does not seem logical, however, to expect that rates will remain stationary while the cost of handling the traffic is continually increasing. As the volume of traffic increases, it may offset in part the greater cost of labor, supplies, etc., but only in part, because increasing tonnage brings with it the demand for additional facilities.

If the appreciation of real estate is to be considered as a part of the income to which they are entitled, the railroads would be better off if their property did not appreciate in value. For, by considering appreciation as income, they would have to pay from their earnings the

Mr. Mills.

full amount of this appreciation with the expectation that at some future time they would receive the interest thereon; but there is no certainty that they will receive this interest, for, at the time of the next adjustment of rates, the physical valuation might be neglected, other considerations being the controlling factors.

If part of the return to which a road is entitled is represented by the non-tangible appreciation of the real estate, there will be, theoretically at least, a deficit in money with which to meet disbursements. It has been suggested that securities can be issued to make up this deficit; but this, in effect, would be to pay operating expenses or dividends in part from the sale of stocks and bonds. It would hardly be equitable to ask a stockholder to waive his dividends wholly or in part because the real estate of the company was increasing in value, knowing that probably it will never be of any benefit to him in the matter of dividends or in enhancing the value of his stock.

The appreciation of real estate is no more a part of the fair return to which a railroad is entitled than losses incident to the enterprise are a part of the expenses on which rates are to be based. If the consumer does not guarantee losses, he is not entitled to the profits. Suppose it was found that the real estate of a railroad was depreciating, would it be considered fair to call this depreciation a part of the expenses to be provided for from earnings? Such a proposal would be decided negatively, for the reason that changes in value are a risk in his enterprise which the investor assumed.

Again, suppose there are two roads, similar in value, except that one owns its real estate and the other leases it at a rental based on its value, provision being made for revaluation. Then, if appreciation is considered as income, the second road will theoretically be allowed the larger rate of income from earnings, for the reason that the expenses of the second road will include the rentals, while the income the first road might be allowed on the value of its real estate will be offset by the appreciation.

As an illustration, take two railroads, one valued at $100 000 000, of which $30 000 000 represents the value of the real estate which has appreciated at the rate of 5% per year. The other road owns no real estate, and is valued at $70 000 000. It uses real estate valued at $30 000 000, paying therefor as rental 6% on its value. It is assumed that each company will be allowed to earn 6% on its valuation. The first road will be allowed to earn $6 000 000, but in this income will be included $1 500 000, which has been the yearly appreciation on its real estate, leaving a balance of cash available for interest and dividends of $4 500 000, or 4½% on its value. The second road will include the rentals in its expenses and will be allowed to earn 6% on its value.

Theoretically, then, if the appreciation of real estate is considered as income, the road which owns its real estate is at a disadvantage as

compared with one that has no such investment, but pays a rental for its use. The word, theoretically, is used because regulation of railroad earnings with any degree of precision by changes in rates is impracticable. Railroad rate regulation is a more complicated problem than in the case of public service corporations with no competition and with service limited to a comparatively small area. Mr. Mills.

To consider the appreciation of real estate as income is confiscatory in character, for the reason that it deprives the owner from any benefit from the future appreciation of the real estate. If he pays for it yearly out of the "fair return" on the chance of getting interest on it some time in the future, the appreciation of his real estate has been practically confiscated.

Briefly, then, for the following reasons, appreciation of real estate should not be considered as income:

It is indeterminate and speculative;
It is not a tangible receipt;
It is different in character from the depreciation of the physical structure, due to wear and tear, for it is a matter of price which may advance or decline.

Such a practice would have the effect of giving the consumer the benefit of the profits due to appreciation, without requiring him to contribute to the losses of a similar character.

It would create a deficit, theoretically at least, which could be overcome only by the sale of stocks or bonds, which, in effect, would be to pay expenses or dividends in part from the sale of securities.

It is confiscatory, because whenever a property is sold the owner is entitled to its full value, whereas if he is required to pay for the appreciation of his real estate, he is deprived of a part thereof.

J. M. SCHREIBER, M. AM. SOC. C. E.—The speaker is particularly interested in the section of the Committee's report relating to depreciation, because he has been identified with similar work undertaken by the American Electric Railway Association. About three years ago, that Association, appreciating the importance of depreciation, through its allied associations, the American Electric Railway Engineering Association and the American Electric Railway Accountants Association, appointed a joint committee of six members, comprising three accountants and three engineers, to investigate the subject. This Committee is still in existence, and is known as the "Joint Committee on Life of Railway Physical Property". The subject was taken up with serious thought and energy, and sincere and earnest endeavors were made, in order to comply with its purpose. The data, secured from the properties with which the individual members were connected, were not only examined, but the Committee got in touch with qualified representatives of almost all the large electric railway companies in the Mr. Schreiber.

Mr. Schreiber.

United States. Amplified inquiry forms were sent out and personal solicitations were made, in an attempt to obtain figures expressing the life of railway physical property, or definite tables which would accomplish the same results.

In general, it was found that those having practical experience, and, in many instances, the responsibility of a particular item of railway property under investigation, felt that any attempt at present to express the life of railway property explicitly, was at best a guess.

After three years of study of the life of railway physical property, from every source obtainable, including the accumulation of a more or less complete bibliography on the subject, this Joint Committee reached the following conclusions:

(1) That the basic elements which determine the life of railway physical property which affect its usefulness are:

(*a*) Use,
(*b*) Climatic and soil conditions,
(*c*) Maintenance,
(*d*) Inadequacy,
(*e*) Obsolescence,
(*f*) The human element,
(*g*) The public demand, and
(*h*) Earnings.

(2) That it is not practical, or even theoretically possible, to assemble compositely these several elements into any form of logical "Life Table" that will apply equally in Maine and in California, in Minnesota and in Louisiana, or on different routes or lines of the same system embracing such physical property.

(3) That the ultimate solution of depreciation of railway physical property is insured earnings.*

It has happened that a great many of the points covered in the conclusions cited have practically been acquiesed in by those who have discussed the subject. It seems that the only way to consider depreciation, if at all, is as suggested by Professor Swain—to designate or set apart a certain portion of the earnings each year to be used for that purpose. Depreciation is an operating problem, and is simply deferred maintenance, and generally, if the amount is proper, allowing for reasonable contingencies, it is used up as operation proceeds year by year. This is because the railway physical property does not have to be replaced all at one time, but on a piecemeal basis, as it were.

Now, as to the important subject of proper general methods for valuation for the purpose of rate-making, it is the speaker's firm opinion that there is only one consistent method to follow, and that is to

* A full report of this Committee, with discussions, may be found in the *Proceedings*, Am. Electric Ry. Assoc., for 1912 and 1913.

ascertain the cost of reproduction new; and, that depreciation should not be taken into account. All the user is concerned about is proper service, and he does not care a whit about depreciation, if the service is not impaired. The speaker desires to call attention to a recent decision of one of the commissions, which is pertinent in connection with the report of the Special Committee on Valuation. It is contained in the Sixth Annual Report of the Public Service Commission of Montana for 1912 and 1913, in the case of J. F. Edwards *vs.* The Helena Light and Railway Company, in which the Commission says: Mr. Schreiber.

"Assuming that rates were being made for a new plant, it would be the total capital that must be considered as entitled to bear interest, as there would be no accrued depreciation. Depreciation is a liability against the property, which must be accounted for, but in making allowance for future depreciation, it is not the intention to provide for accrued depreciation, which it is assumed, has been taken care of. To simplify the matter, let us assume that an investment is made in 1903 of $100,000 under a twenty-year franchise, rate of interest allowable 10% per annum, and figuring 5% per annum depreciation. At the end of ten years, or in 1913, the property will have depreciated $50,000 and has a remaining value of a like amount. Then, if rates are made, based on the depreciated value, they must be one-half of the original rates, although the service may be just as efficient as it ever was, and in ten years more, the physical value of the plant would be nil, and likewise upon the same basis of reasoning, the utility would not be permitted to charge anything."

In conclusion, the speaker appreciates thoroughly the great task undertaken by the Committee on Valuation for the Purpose of Rate-Making, and thinks it deserves a great deal of credit. He agrees with a considerable portion of the report. As a member of the committee of the American Electric Railway Association, he is quite sure that it will be very glad to co-operate in every way with the Valuation Committee, and furnish any information and data on the particular subject of depreciation at its disposal. The speaker would also suggest that the Committee confer with the National Electric Light Association, which no doubt would also be willing to furnish pertinent data on the subject.

Certainly any conclusions on the whole report should not be accepted until the utilities, which are so vitally interested in the question, could at least have an opportunity to present their views properly.

J. P. NEWELL,* M. AM. SOC. C. E. (by letter).—Should depreciation be taken into account in fixing rates? If by this is meant, "Should rates be reduced as the depreciation increases?", the question must be answered in the negative. Assuming that the service rendered remains the same in quantity and quality, the rates should remain the same. Mr. Newell.

* This discussion was presented before the Portland, Oregon, Association of Members of the American Society of Civil Engineers, at its meeting of April 4th, 1914.

Mr. Newell.

Any other policy certainly would not be attractive to capital, nor would it be of advantage to the public. As the total return during the life of the plant must be the same in any case, diminishing rates would require a higher charge in the beginning. Still, depreciation must be taken into account for the benefit of the company, not of the public, for depreciation is not a penalty assessed against the company for the deterioration of its plant; it is an amount added to the rates to repay the company for this same deterioration.

Much of the confusion of thought concerning depreciation arises from failure to distinguish between the standpoint of the public and that of the management. The prudent manager of a public service corporation will open a depreciation account, and will take good care that the amounts credited to it do not pass to the stockholders in dividends, leaving him unable to provide for renewals and replacements when needed. That, however, is of no interest whatever to the public. Fix rates that will insure capital a fair return, and renewals are certain to be taken care of. Even if the existing company dissipates its capital and is unable to replace it, some new company, knowing that a fair profit is assured, will be found ready to step in with new capital and take up the work.

The rate-regulating power need concern itself with only one question: At what figure must rates be fixed so that, at the end of the life of the plant, the owners will have received the full amount of the operating expenses, the value of the plant, and a fair return on their investment?

One method of finding the answer to this question is that used in dealing with a peddler: Find out the least he will take and give it to him. If we can do this, we need only divide the total amount by the assumed life of the plant, and we have at once the annual charge for service. The capitalist may put the receipts in his pocket, divide them up in his accounts in any way which suits him, and spend them as he pleases; and it is in accordance with this principle that the fairness of all rates must ultimately be judged. The least that capital will take, under conditions such that all capitalists are free to invest, is what it should be allowed to charge.

It would take years, in many cases decades, however, to apply this method. Besides, we must deal with many utilities, built under different conditions, the owners of which are not free to act on the above principle. We must deal justly with these men, who are, in a sense, at our mercy, or later we shall find ourselves at the mercy of other capitalists who will refuse to invest in other utilities which we need.

Some contend that rates should be based on the reproduction cost new and not on the depreciated value. True, as the rates must be sufficient to return to the owner an amount equal to this cost. The owner's profit, however, cannot justly be based on this reproduction

cost new, if part of it is returned to him annually through the depreciation allowance. Mr. Newell.

Compare the case with that of a loan. Suppose B borrows $100 from A at 6% interest, the principal to be repaid in 10 years. Anticipating B's inability to pay the whole amount at one time, A insists that B, in addition to the interest, shall make an annual payment on the principal. At the end of the first year B will then pay $10 plus interest on $100, or $16. At the end of the second year his payment will be $10, plus interest on $90, and so on to the last year when he will pay the last $10 of the principal and interest on $10.

Certainly no one will contend that A should continue to receive interest on the original $100 for the entire time, on the ground that he expects to make B a new loan at the expiration of that time. Neither should an investor expect to receive a profit on capital which has been repaid to him. Nor does this depend on the "adequacy" of the depreciation allowance. If that allowance be small, only a small part of the investment is wiped out, if large, there is a larger reduction in the capital; but the principle is the same in either case. If at any time it is found that the life of the plant has been assumed at too high a figure, and the rate of depreciation is correspondingly too low, the remedy is to increase the depreciation allowance, and, consequently, the rates charged the public, and to make this increase sufficient to cover the error for past as well as for future years. Care should be taken to assume depreciation high enough in the first place so that adjustments will reduce rather than increase rates. In fixing the rates of an existing plant, if it can be shown that its income has been too small in the past to produce a fair return, or that the profits have been excessive, the rates should be governed accordingly. If neither of these conditions can be satisfactorily proved, however, we must proceed on the assumption that the plant has been earning a fair return and no more.

Consider the case of a plant fully equipped, with business neither increasing nor decreasing, so that no extensions are required; the cost of reproduction new and the expected life of the plant have been ascertained, and the fairness of the existing rate is to be determined. The rate under consideration produces a gross income which is constant from year to year. The operating expenses are assumed to be constant, so the sum of the depreciation and the profit, or return on capital, the other two elements composing the gross income, is also constant.

If we adopt the "Straight-Line" Method of calculating depreciation, both these factors become constants, also; that is, we have a constant return based on a constantly diminishing capital. There is no inherent injustice in this to either party, but the rate of return on the existing investment must be too low at first, and too high at the last. This is illogical and unnecessary. It opens the way for complaint from the

Mr. Newell.

company in the first period and from the public in the last. It adds also to the difficulty of adjustment, if the assumed rate of depreciation is found to be erroneous.

Let us then assume that the rate of return on the capital remaining in the plant must be the same each year. We now have these conditions: The gross income, a constant, is made up of three parts:

(1) Operating expenses, also a constant;
(2) Depreciation;
(3) Profit.

The sum of (2) and (3) is constant. The rate of profit or return is constant, but, being based on a valuation which diminishes year by year, the actual return also diminishes, and the depreciation correspondingly increases. The value and the life of the plant being known and the sum of the depreciation and the profit being fixed, as stated, it becomes a matter of mathematical calculation only, to assign the proper amount to each. The depreciation must be fixed at such an amount, for the first year, that the depreciation for each year plus the return on capital, based on the depreciated value for that year, shall equal the given sum, and that the sum of all the annual depreciations during the life of the plant shall equal the value of the plant. Solving, we get the rate of return on capital produced by the given rate, and the amount of capital repaid each year.

In the illustration already given of a loan, B pays $16 the first year and $10.60 the last. If, instead, he makes a payment of $13.59 each year, from which the interest due is first deducted, and the balance applied on the principal, he will likewise extinguish the debt in the given time. In the first year his payment on interest will be $6 and on principal $7.59; in the tenth year, the interest will be $0.77 and the principal, $12.82. Similarly, the annual repayment of capital from a uniform rate should increase as the depreciated capital diminishes. There should be no attempt to make the depreciated allowance conform to the actual visible depreciation from year to year. Fluctuations in the observed conditions should be taken account of only as they affect the life of the plant.

The results obtained by this method correspond to those given by the tables accompanying the report of the Special Committee. The Committee, unfortunately, has confused the matter somewhat by presenting a table in which one percentage is used in calculating depreciation, and another for profit. The sum of the results thus obtained not being constant, it follows that rates cannot be constant.

A concrete example will make these principles clearer. Assume a plant costing $100 000, with a life of 10 years, and operating expenses of $6 000 per year, and fix the fair rate of return on capital for this

kind of investment at 7 per cent. This gives all the information needed for the establishment of rates. Mr. Newell.

By the "Full-Value" Method, the annual depreciation will be $10 000, the return on capital $7 000, and the rates $23 000.

The totals for the life of the plant will be:

Operating expenses.....	$60 000
Depreciation	100 000
Profits	70 000
Total	$230 000

It will be seen from Tables 22 and 23 that the depreciated value of the plant at any given time has no bearing on the rates. The whole matter of depreciation is considered, once for all, when the length of time is determined during which the value of the plant must be repaid out of the rates. Any further evidence of depreciation is important only as indicating error in fixing that time.

In all the previous discussion, the effect of renewals and replacements has been ignored; but these do not affect the principles stated. The item replaced has been depreciated to zero condition, and then renewed to 100% by the introduction of new capital. The life of the plant is a composite of the lives of all the parts, in proportion to their respective values.

Fair rates may also be determined by the Sinking-Fund Method, provided the profit is based on the reproduction cost new, and the interest on the sinking fund is calculated at the same rate as the profit. Under this method, instead of handing to the owner each year certain varying amounts, the sum of which will equal the value of the plant within its life, and which are to be deducted each year from the capital on which a profit is permitted to be earned, a uniform amount, less than the average of those above, is assumed to be set aside each year. These uniform amounts, at compound interest, will equal the value of the plant at the end of its life, but they will not do so unless the owner continues to apply his industry and skill to them. As the capital is gradually transferred from plant to sinking fund, but remains always engaged, the fair profit must be based on the full, and not on the depreciated, capital. This is true, no matter by what means the owner chooses to make the sinking fund earn the required interest.

It is commonly assumed that interest on a sinking fund should be calculated at a very low rate, such as money can earn with no risk and with the minimum of attention. To the writer this appears clearly erroneous. The owner is paid not only for the use of his money, but also for his skill, industry, intelligence, and risk. These factors he is paid for applying to the entire capital, whether it be all in plant,

Mr. Newell.

TABLE 22.—By "Straight-Line Depreciation."

Year.	1	2	3	4	5	6	7	8	9	10
Operating expense	$6 000	$6 000	$6 000	$6 000	$6 000	$6 000	$6 000	$6 000	$6 000	$6 000
Depreciation	10 000	10 000	10 000	10 000	10 000	10 000	10 000	10 000	10 000	10 000

or partly in sinking fund. As he is paid, through the rates, for such management as will cause the sinking fund to earn the given rate, he cannot well claim that it is actually earning less. Mr. Newell.

The best possible proof of the correctness of these two methods of calculating fair rates is to be found in the fact that, though differing widely in principle, they give identical results.

If the principles governing depreciation have been correctly stated, it follows that as far as rate-making is concerned, the public service corporation need concern itself about "depreciated condition" not at all, but about the rate of depreciation a great deal. Proof of a short life for the plant will do more than anything else to justify high rates. Such proof will likewise establish a low depreciated value, which may affect the company's interests in the way of sale or taxation values, or borrowing power, but not in respect to rates.

The appraiser, instead of constructing mortality tables by which to determine the condition percentage, should observe conditions in order to make up mortality tables. Every item of the appraisal should have given its age and expected life, as well as the reproduction cost. Depreciation can be expressed only by the ratio of remaining to total life, as depreciated value is a function of the rate of return on capital as well as of length of life. The composite length of life of the plant must then be determined by calculation, the operating expenses by the company's accounts, and the fair rate of return by the judgment of the public service commission. From these three factors and the reproduction cost new, rates properly to be charged the public can be calculated by either of the methods discussed.

The writer prefers the Equal-Annual-Payment Method, because it takes account of all the facts all the time. It gives a "present value" which is also the true value for purposes of sale and taxation. As it reckons profit on depreciated capital, it is more nearly in accordance with Court decisions, and is more likely to meet with popular approval.

GARDNER S. WILLIAMS, M. AM. SOC. C. E.—On its appointment, this Committee was designated a "Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities." The speaker regrets that thus far the Committee does not seem to have risen to the plane required for such a consideration of the problem submitted, as its importance demands, and as some, at least, of those who stood sponsor for the appointment had reason to anticipate. Mr. Williams.

In the speaker's understanding, the Committee was "to formulate principles," not to accept rulings already formulated under the exigencies of particular conditions, especially as in the majority of cases those rulings have been formulated by persons far less qualified to

Mr. Williams.

deal with the subject, in its entirety, than it is proper to assume the membership of this Committee to be.

Further, it is the belief of the speaker that neither the Committee, nor any one else, should accept dicta as decision, nor opinion as law; or even accept decision as final. For 300 years the Courts steadfastly refused to admit opinion evidence, and it is within the memory of some of the members of this Society when it was absolutely excluded; but where in America to-day is the higher Court that does not receive and consider it?

To this Committee, in the discharge of its prescribed duty, as the speaker understands it, the existing interpretations of the law and the wording of special acts are of no consequence, until the Committee, after careful and mature deliberation, is prepared to say that those interpretations and the wording of those acts are just, equitable, and fair to all concerned in all cases. If the work of the Committee were to have been bounded and controlled by legal decisions and legislative enactments, it should have been empowered to employ those expert in the law to perform its work, or the whole question should have been referred to a bar association. If, in dealing with this subject, the American Society of Civil Engineers cannot get back to, and enunciate, those fundamental principles of rights and justice that underlie and overrule all man-made law, then, in the speaker's opinion, again, this Society should let this subject alone.

In importance, the question referred to this Committee overshadows every other question this Profession is now or has ever been called on to consider. Of the estimated fixed wealth of the United States, exclusive of real estate, nearly 60% was invested, in 1904, in properties within the purview of this Committee, and the investment therein has increased 50% in the last 10 years. On all hands the rumblings of a coming strife between the masses and the classes are to be heard. State socialism is being advanced as a panacea for the ills bred in ignorance and nurtured in indifference, and engineers, trained by the responsibilities of their profession, are the one class fitted to rise between the contending forces and present a correct and safe plan of future procedure. To no class other than themselves does the advance of socialism presage such disaster. Socialism stands for the mediocre man, for the ignoring of special ability, and the suppression of more than average energy. This Profession exists as the foremost exponent of special ability and increased efficiency. The two ideas are absolutely inconsistent and incompatible, and the engineer must recognize the fact and enter the combat accordingly. He must qualify himself to explain clearly to his fellow-citizens the true relations between capital and labor, and the rights and privileges of each, and must take the position, in the community, as a leader

Mr. Williams.

of its thought, for which his training in exact reasoning should have prepared him.

The valuation of the property of public utilities may be undertaken for any one of five different purposes, which, in the order of their justification, may be stated as follows:

A.—For the purpose of forced acquisition;
B.—For the purpose of sale or purchase;
C.—For the purpose of taxation;
D.—For the purpose of issuing or limiting the issuance of securities;
E.—For the purpose of establishing rates.

(*A*).—In valuation for the purpose of forced acquisition, or, as it is commonly called, condemnation, the provisions of our National and State Constitutions set forth the principles to apply, and no one questions the privilege of sovereignty to exercise the right of eminent domain when such exercise is found to be for the general welfare. The long-established rule that the owner is entitled to the fair value of his property, unaffected by past or proposed legislation to the benefit of the purchaser, has been interpreted to mean that he is entitled to receive the price on which a willing purchaser and a willing seller would agree, for the property to be conveyed. It may be justly questioned whether this is in all respects a fair treatment of the owner, who may not be a willing seller, preferring to any other the particular industry in question as a matter either of choice or of sentiment. Whoever does not recognize the force of sentiment is unfit for citizenship in either a democracy or a republic. Charles Kingsley, as an Englishman, expressed a doubt of its existence as applied to inanimate concepts, and Edward Everett Hale gave an American's answer in "The Man Without a Country." To him, bereft of sentimental association by the appropriation of the result of the labors of perhaps a lifetime, compensation for sentiment is due, and must justly become an item of value recognized in the exercise of the right of eminent domain.

(*B*).—In valuation for the purpose of sale or purchase there again can be no question of the right of procedure, and, as both parties are interested in obtaining the same information, the rules of accounting are to be followed naturally, and the result arrived at should be the price on which the willing seller and the willing buyer can agree.

(*C*).—In valuation for the purpose of taxation the result is influenced by other conditions than in the two former cases. For many years it has been a principle of taxation in America that taxes should be levied only on physical properties, and it is as yet in only some of the States that a deviation from this principle exists. If it

Mr. Williams.

were not for this restriction, the value for the purpose of taxation should be the same as for purchase or sale.

(*D*).—In valuation for the purpose of issuing or limiting the issuance of securities, there is first encountered a question of right to value. So far as the owner's inquiry into the value of his property for his own information, or for that of the proposing purchaser of its securities, is concerned, there can be no question; as to the right of sovereignty to step in and demand or pass on such a valuation, there may be grave question. Waiving for the time the consideration of such right, however, there appears to be no reason for this valuation to be different from that for purchase and sale. Indeed, the two cases are similar in all respects, for the bondholder may be conceived of as buying the plant in whole or in part, and as allowing to the owner for its operation and maintenance so much of its income as exceeds a certain stipulated sum.

(*E*).—Finally, the right to a valuation for rate-making by the State, it must be admitted, is only to be derived by an extension of the powers of Government never contemplated by the founders of our commonwealth, and if by the term "investment" the Committee means financial investments, the speaker most emphatically takes issue with the statement on page 11 of the report that "it would be entirely just and equitable, and it is highly desirable to provide by law that future public service properties should be valued on the basis of their actual reasonable existing investment, and to determine or limit rates upon such a valuation if the service rendered permits," and he further emphatically denies that there is either justice or equity, or even common sense or practicability, in the proposition therein advanced.

As an example of the inadequacy of cost to determine value, consider the case of a horse about to enter a race for which a purse of several thousand dollars is offered, and that his ability to win the race is assured. Would any one say the value of that horse at that time was represented by the cost of siring, foaling, raising, and training him, plus, if you will, an allowance for deterioration of his dam?

Following the suggestion of the Committee to its logical conclusion, it results that the illy devised, illy designed, expensively constructed, and extravagantly operated plant is put on a par in earning capacity with one prudently devised, well designed, carefully constructed, and economically operated. In other words, the Committee omits that greatest element of value, in all business enterprise, that element without which there could be no variation in value in the same or similar situations, that element which lies at the foundation of all progress, brains. Of all persons on earth, the engineer should be the last to overlook brains. Brains, and brains only, differentiate

Mr. Williams.

him from the laborer in the street, and our patent laws recognize the compensation due to brains.

Take the first entry of brains into a proposition, its conception; if the idea be novel and the business developed on it be successful, then the idea was valuable and is a part of the investment. Let it be a case of a water power; some one conceives the development, some one works out the general scheme and, for this service, usually receives or retains a portion of the corporate stock for which he makes no other payment. In the search for tangible property, behind the investment, this block of stock will be termed "water", but it is really "brains", and is just as much entitled to recognition as a factor in the development as the money actually paid to labor for the construction of the work; but where, beyond the value of the time spent, is there recompense allowed for this item in the scheme of the report?

Again, a corporation secures the services of an engineer who is an expert, and gives him an interest in the property in addition to the fee for his services. He produces for them a plant capable of converting the power of Nature to the use and convenience of man with a higher degree of efficiency than has been accomplished in any previous plant, and besides doing so, he reduces the construction cost per unit of capacity. Are not the brains of that engineer as put into that plant entitled to be counted as part of the investment in that plant, and is it not right and proper that this plant economically constructed and economically operated should be entitled to earn a higher rate of interest than the plant thrown together haphazard, wasting perhaps 50% of the natural energy it is purposed to convert?

These are some of the questions to which one looks in vain for an answer in the Committee's report, and they are the questions for which a formulation of correct principles of valuation must provide.

The programme outlined in the report, and in every discussion of the subject with which the speaker is familiar, puts a premium on bad judgment, bad design, bad construction, and bad management, and a penalty on their opposites. To such a programme neither the engineer nor the public can afford to subscribe.

If a property be only worth its cost, what is the inducement to produce it? Take, as an example, the land needed for a reservoir site. A part is secured at the price of ordinary farm land and the last few parcels at three or four times that price. When all that land has been brought together into one complete whole, is it worth no more than when scattered in isolated parcels under diverse ownership? Is it worth no more as such a whole than the cost of its acquisition?

Is a watch ready to be wound and to run only worth the cost of its component parts and the time of the mechanician who puts them together?

Mr. Williams.

The purpose of the public service corporation is to serve. The value of a service has only this connection with its cost, that it must not be less than the cost or the service cannot be rendered, and the compensation to be demanded must not be greater than the value, else no one will accept the service.

To determine properly the rate for a service, its value to the recipient must be established, just as the value of any other article or concept to be marketed must be established.

This is a broad question, a hard question, and it involves the same problems as those confronting the investor every day, that this business may be highly lucrative, while that may be a losing venture, when, in either case, the worth of the physical property has no determining influence on the value of the project.

There are in a certain locality two water-power plants designed to serve the same community. One cost about $300 per horse-power of machine capacity and the other less than $100, on the same basis. In one of them the advantages of expert training and brains were utilized to the utmost, and the plant has proved a model for numerous later ones scattered throughout the country. In the other the brains that entered were used mainly in copying the mistakes of previous designers and in building up a huge physical investment on which bonds could be sold. The latter concern is bankrupt, the former is paying excellent dividends. If the rules laid down by the Committee be accepted, the bankrupt concern would be earning a mediocre return on a bad investment, and the other would have its earnings reduced one-half, while the customers of the one plant would pay three times as much as those of the other for the same service. In its work the Committee, like many of our public service commissions, seems to have started from the wrong premises. Even in dealing with the value of physical property alone, which, by the way, the Courts have usually held to be only an indication of value, there is apparent a misunderstanding of depreciation. The substance of the definition usually accepted for this term is the value of the service already rendered by an article not new. In a valuation, this has nothing to do with the case. So far as its value is concerned, whether the property be a railroad track or a jack-knife, its past service is of no interest; it is its future possibility of service that is involved. The true definition of depreciation as used in valuations then is as follows:

"Depreciation is the difference between the present worths of future service and scrap value of a new article, and of the article under consideration."

If this definition be gotten clearly in mind, it will help in wiping out some of the difficulties contained in the subject of valuation.

GEORGE F. SWAIN, PAST-PRESIDENT, AM. SOC. C. E.—The speaker would say at the outset that he has read this report with greatest interest, and considers it, in regard to everything except the matter of depreciation, the most sane, sensible, and logical discussion on the subject that he has seen. It is clear, forcible, fair, and accurate. It presents the various points impartially, at the same time giving the conclusions which the Committee deems justifiable, and with which, in most cases, the speaker cordially agrees. It brings together a great number of facts and illustrations drawn from experience which have never been collected before, and which cannot fail to be of great value in the future consideration of the subject. The thanks of the Society are cordially due to the Committee for its work. Mr. Swain.

With reference to the question of depreciation, however, the speaker believes that the views of the Committee are lacking in clearness, that they involve confusion of thought, and are misleading. He, therefore, wishes to give his own views on the subject, though he fully realizes that he is quite as likely to err as the members of the Committee. This subject of valuation is one which is in the making, and it must be expected that opinions, both of individuals and of the Courts, will experience modifications as the subject becomes more definitely understood and the principles definitely established.

The question of depreciation is twofold:

First.—What is the actual depreciation?

Second.—What value of the property shall be taken for the purpose in view?

With reference to the actual depreciation, this, as every one recognizes, is not a matter of computation or theory, so much as of actual inspection. The actual depreciation will depend on the maintenance. If a steel bridge has been kept well painted and in good repair, it may not have depreciated at all; that is to say, it may be exactly as good as new, although, on account of obsolescence, or, in this case, the fact that increasing weight of rolling stock may require a new structure before the old one is worn out, it may be less suitable for present purposes than when built.

Actual depreciation, therefore, depends on maintenance, and is to be determined largely by inspection.

With reference to the value of the property which is to be taken, the speaker is glad to know that the Committee definitely states that this value depends on the purpose in view, and may differ according to that purpose. It is true, of course, that a public service corporation would generally be willing to have the same valuation used for taxation as for rate-making, provided a fair value for rate-making purposes is allowed, because the rates should be adjusted so that a fair return will be allowed to the owners after taxes have been paid. This being

Mr. Swain.

the case, it is evident that it can make no difference to the company how high the taxes are, if such fair return on a fair value is allowed. So far as physical property is concerned, however, a valuation for taxation would not necessarily be the same as for rates. One instance alone will illustrate this point. The construction of a railroad station may have required the taking of a piece of city property with the buildings on it, the latter having been afterward destroyed. A fair valuation for rate-making would include, of course, the cost of the buildings, but these having been destroyed, there is no taxable value to represent their cost except an intangible value. If, therefore, the same value is used for rate-making as for taxation, then, so far as taxation is concerned, this value is not that of the physical property alone, but includes an intangible element.

Coming now to the main point which the speaker wishes to discuss, the burning question with regard to the value which is to be taken as the physical value for purposes of rate-making, to which the report of the Committee is limited, is the question whether a fair return should be allowed on the cost-of-reproduction-new, or on the cost-of-reproduction-new-less-depreciation. With regard to this, the report of the Committee states definitely in several places that the cost-of-reproduction-new-less-depreciation should be used. For instance, on page 10, it is stated:

"The result obtained after making deductions for obsolescence would be the value of existing items of property new, which should be further diminished by the net amount of the depreciation of the existing property."

Again, on page 19, the report states:

"In order to complete the valuation by this method [reproduction-new], it is necessary to make a deduction from the values obtained as above stated, for the net accrued depreciation of the physical property due to age and other causes."

Once more, on page 32, it states:

"A depreciation allowance is, in effect, a payment from the rate-payer to the corporation of a part of its investment, and such part of the investment as has thus been repaid should not appear in subsequent valuations of the property."

Again, on page 72, the distinct statement is made: "The depreciation value of property should be basis for rate-making."

However, in the Addendum to the report, page 3, it is stated:

"That there are certain methods of compensating for the loss of value due to the depreciation of perishable property, which require that the property be valued as if new in order that injustice may not be done to the owner of the property, but that there are other methods

Mr. Swain.

of compensating which require that the property be valued at less than its value new, or, in other words, at a depreciated value, in order that injustice may not be done to the public."

In other words, the Committee definitely states here that whether the cost-of-reproduction-new or cost-of-reproduction-new-less-depreciation shall be taken depends on the method of depreciation allowed.

In the speaker's opinion, the method of depreciation to be allowed is an accounting problem, the object being simply to set aside out of earnings each year such sum as may enable all renewals in kind to be made without any increase of capital.

The speaker contends that a depreciation allowance may be considered, not, as the Committee states, as "a payment from the rate-payer to the corporation of a part of its investment", but that it is a payment of the same kind as one for maintenance. It is a payment to ensure the permanent maintenance of the plant in kind without increase of capital. Moreover, it is a payment to the corporation and not to the stockholder who has invested the money. It is a payment which should not reach the stockholder, but should be held by the corporation for a specific purpose, *viz.*, the indefinite perpetuation of the property.

In general, the proper method of allowing for depreciation appears to be clearly the sinking-fund method, because that is most favorable to the public and equally favorable to the corporation.

The Committee is perfectly right in stating (Addendum, page 3): "that the owner of a public utility property is entitled to have the rates made high enough, under normal conditions, to pay for the lessening value of the perishable property, so that when such property goes out of use he shall have received, not only a fair return for the use of the capital invested in such property, but shall also have the capital invested in it paid back to him," except that the original capital should not be paid back to the investor, but should be held by the corporation for renewal when the time comes.

In other words, capital honestly and properly invested should not only receive permanently a fair return, but the rate should be high enough to return to the company an additional amount each year, which, if safely invested, will amount, when the property requires renewal, to the cost of renewing it in kind, that is, as it was originally, without any additions or betterments.

The sinking-fund method, as previously stated, provides for this with the least payment from the rate-payers. The latter pay each year, not only enough to give a fair return on the capital, but a sum which, if placed at interest, will amount to the cost of renewal when renewal is necessary. These payments for depreciation by the rate-payer should be allowed to earn interest, and if so allowed, the yearly payments will

Mr. Swain.

be smaller than if not allowed; the rate-payers are just as much entitled to claim that interest should be allowed on their payments for depreciation as the owners of the property are entitled to claim that they should be allowed a fair interest on their investment. All that the company is concerned about is that it should have funds in hand, obtained from rates, which will enable it to pay for renewals as they are necessary. All that the rate-payers are concerned with is that they shall have contributed each year the smallest sum necessary to bring this about, and this is the sinking-fund depreciation.

Now, when the rate-payers have paid rates high enough to allow a sinking-fund depreciation, they have no further interest, as rate-payers merely, in the question, nor is it of any consequence to them, as rate-payers, what the company does with the depreciation allowances which they have paid. It makes no difference to them whether the company puts these depreciation allowances in a fund, whether it uses them for extensions to the property, or whether it distributes them as dividends. Having contributed these sums, they are entitled to claim, and should claim, and the Courts will sustain them in claiming, that when the property or item under consideration is worn out, it shall be replaced by the company at its own expense, that is to say, without further contribution from them, as it was before, without any increase of capital on which future earnings are to be made. The rate-payer, of course, is concerned that the depreciation funds should be safely invested, so that they will be available when the time for renewal arrives, and, of course, it is for his good that the rate of interest allowed in figuring the depreciation allowance by the sinking-fund method should be as high as is safely practicable; but as long as the company must replace every item of its property in kind, as it wears out, at its own expense, and is in a position to do so without injury to the service rendered, the rate-payer has no further interest with what is done with the depreciation allowance. As a citizen, or as an investor, he may be concerned in this matter, and would object to having the depreciation allowances paid out in dividends, as this course would enable the stockholders to receive dividends greater than a fair return and then, perhaps, sell the property on the basis of such exaggerated returns to other investors who might not realize that the former owners had made no provision for renewals. Proper accounting and financing, therefore, require that only a fair return shall be paid in dividends, and that the depreciation allowances shall be invested or held in some manner which will insure their being used for the purpose for which they were paid in. This is for the interest of stockholders rather than for the interests of the rate-payers, as such.

Mr. Swain.

It will probably not be questioned, therefore, that the stockholders of a property built to-day are entitled to a fair return, permanently, on the money originally invested, if honestly and properly spent, and that the rates should also provide for the accumulation of yearly depreciation allowances. If this is so, is it not then clear that the cost-of-reproduction-new should, so far as a physical valuation is concerned, be used as the basic value on which earnings should be secured? In order to answer this, it is at this point necessary to see clearly the relation between the reproduction method and the cost-new method.

In a concern organized to-day under public supervision, with accounting methods also under supervision, there would never be any necessity for using the reproduction method or for making any valuation. Its stockholders would be allowed to earn a fair return on the cost, plus depreciation allowances; renewals would be made in kind without increase of capital, and all betterments would be charged to capital. If there should be a lack of a fair return in early years, any such deficiency would be included under cost of developing the business, and in subsequent years a return would be allowed on this also. Such a procedure would not prevent an unwise venture from failing, for an increase of rates might diminish net earnings, there might be a continued cessation of dividends, and the concern might eventually collapse; but a concern wisely planned and economically built would prosper, and its stockholders would have no cause to complain. There would be no questions as to the appreciation of land; if, through the growth of the community, the value of its lands should largely increase, the concern could not be bought out by another concern with the expectation of fair return on the increased value, because the original cost would govern.

In the case of most corporations, however, especially railroad corporations, the original-cost method is not possible, because the data are not available. What is sought now in making a valuation, is a basic physical value from which to start new and on which, in future, to base earnings. For this purpose no other method is available than the reproduction method. The cost is estimated of reproducing the property new at the present time. This is taken as the basic physical value of the property, just as the original cost, with subsequent betterments, would be taken as the basic value if that method were available. The speaker does not understand that it is at all contemplated that the reproduction method shall be applied from time to time to the same property and the rates modified according to each valuation; he does not believe in such a procedure. As he conceives it, a valuation is to be made once for all in order to get a basis from which to start new, after which, proper accounting methods will be required, renewals in kind must be made from earnings, better-

Mr. Swain.

ments capitalized, and rates can be regulated in the future without another valuation. The reproduction method is used because it is the only possible method of general application.

The kernel of the whole matter, therefore, it seems to the speaker, is the question whether the cost-of-reproduction-new should be taken and used as the equivalent of original cost. Probably few will question the statement that, when available, the original cost, allowing for deferred dividends, is a proper basis of physical valuation on which earnings should be secured. Stockholders who invest their money honestly and intelligently in a public utility concern, are entitled to receive a fair return on that cost permanently, together with operating expenses, taxes, and a depreciation allowance, and any deficiency of dividends is entitled to be capitalized. Depreciation should not be deducted in finding a physical value on which to base proper earnings. The original cost is the proper basis, and is the basic physical value on which stockholders should receive a fair return.

Now, if the cost-of-reproduction-new is also a proper basis, it must give the same result in cases where both are applicable. In the case of a new concern, the original cost would be, of course, the cost-of-reproduction-new. The same would be true in a concern in which the cost-new could be ascertained, and the books had been properly kept, and in which costs had not altered since construction. There are many corporations, however, in which the original cost method is impossible of application by reason of lack of data. In this dilemma, as the speaker understands it, we turn to the cost-of-reproduction as the only other available method. In using this method we are necessarily thrown largely on surmise and judgment, but no other method is possible. The costs have changed since the property was built, and no one can say with certainty that the cost-of-reproduction-new will be greater or less than the original cost. In the case of our railroad companies, lands were granted them by the public, and these, together with lands which they bought, have largely increased in value, mostly by reason of the existence of the railroad itself. Lands owned by private owners have likewise increased in value. It seems to be no injustice to allow the corporation the benefit of an increase in value which has come from its own existence, and which is no greater than the increase in value which its existence has brought to the property of private owners. Moreover, in the case of many of our railroad companies, if not of all of them, dividends were deferred for many years, reorganizations have taken place, and a great deal of money has been spent in betterments and charged to operating expenses; so that, as stated, the cost-of-reproduction-new cannot be said to be greater or less than the original cost, if the latter could be accurately ascertained.

The statement then is this: The reproduction-new method gives the same result as the original cost method where both are applicable; in

this case the original cost is a proper basis and would be used. Must we not, therefore, in cases where the original cost method is not applicable, assume the cost-of-reproduction-new to give the same result and to be used in the same way as the original cost would be if we could find it? The answer to this question appears clearly to be in the affirmative. Mr. Swain.

The Supreme Court, in the Knoxville decision, held that if, in the past, rates had not been high enough to provide a proper return and a proper depreciation allowance, "the true value of the property * * * cannot be enhanced by a consideration of the errors in management which have been committed in the past." This rule should work both ways; and if, in the past, rates have been so high as to have permitted excessive profits, or if the public has given lands for nothing, then the value of the property cannot be reduced by a consideration of the errors committed by the public in "the past", even if we choose to designate as errors a policy which, on the whole, has resulted in a wonderful national development and prosperity. We are starting new with a value of the property, and in the speaker's opinion, there is no method which will be uniform in application, and will reconcile all differences of conditions, except to take the cost-of-reproduction-new, and to consider that this is to be used exactly as if it were the original cost.

The first principle on which the speaker has based his conclusions, therefore, is that the cost-of-reproduction-new is to be taken and used in the same manner as the original cost. If this be true, it is perfectly clear that the undepreciated value should be the value on which a fair return should be based, just as the original cost, when available, should be the fair value on which a reasonable return should be based.

Of course, it must not be forgotten that a physical valuation is only one of the elements to be considered in deciding on rates or any other question. Neither the original-cost alone, nor the cost-of-reproduction-new alone, is necessarily the present value; but we are not discussing this question here. We are simply endeavoring to decide what physical value is the proper one to consider as the basic one on which, so far as physical value is concerned, fair earnings are to be made.

The Committee has apparently been governed in its attitude by the assumption that the Courts had finally and definitely decided that the cost-of-reproduction-less-depreciation must be used, and its endeavor has been directed toward finding a method by which the same total annual return would be received by the corporation as by using the original cost.

This result is accomplished by the Committee's method only in case the rate of return on the investment and the rate of return on the sinking funds are the same. If the sinking funds are invested in extensions of the plant, this may be true, but in many cases the sinking

Mr. Swain.

funds cannot be invested in the plant, and the rate of return on the sinking fund would be less than that received from the investment. Indeed, inasmuch as the sinking fund must be assumed to be invested safely above all things, there seems to be no reason for assuming a greater rate of interest on it than the company receives for its cash, or the rate of interest for time loans, which, in general, would be less than a fair return on the investment. In this case, the Committee's method, as shown by Column 7 of the table on page 34 of the report gives a smaller return, except in the first year, than is fair. It results, therefore, in confiscation.

The object of the Committee, however, is perfectly clear and quite praiseworthy. It assumes that two things have been finally and irrevocably settled by the Courts:

First.—That the cost of reproduction-new-less-depreciation must be used as a basis;

Second.—That the mistakes of the company in the past, in not charging rates sufficient to provide a fair return plus a depreciation allowance, cannot now be rectified.

These two findings are justified in the decision of the Supreme Court in the Knoxville case. It must be remembered, however, that the Courts, being human institutions, are subject to error; that every Court has had its decision reversed probably more than once; and that the Supreme Court of the United States has reversed its own position in a number of instances.

Much is said, in discussing this subject, as to respect for the Courts. The speaker believes that there is no one who has greater respect for them than he, but it is very important to understand clearly what respect for the Courts implies. It certainly does not imply agreeing in all cases with their decisions, or even accepting them without argument, if we believe them wrong. Judges, like those who are judged in this world, are human, and it would be less respectful to attribute to them superhuman attributes by assuming them to be always correct and infallible, than to admit their fallibility. Proper respect for the Courts means that we should believe our judges to be honest, faithful, disinterested men, honestly striving to administer justice, and that we should accept their verdicts when rendered, if we have to and are obliged to act on them; but that does not prevent us from fighting with all our might and main to convince them that they are wrong, if we believe such to be the case. The present subject is in the making, and it is quite possible, if not probable, that the Supreme Court may reverse its finding with reference to the facts referred to. Assuming those findings to be correct, however, the Committee pursues a perfectly consistent course. This may be illustrated graphically:

Mr. Swain.

In Fig. 8 let OY be the first cost of a piece of property, and OX its life, say, 10 years. The curve of the sinking-fund depreciation is shown by the curve, YX. ab is the annual payment which in 10 years will amount with interest to the original cost, or the assumed cost of reproduction. At the end of 5 years, five annual payments have been made, which, with interest, amount to $a_5\ b_5$, leaving $b_5\ x_5$ as the assumed depreciated value; $c_6\ b_6$ is equal to ab plus the interest for a year on $a_5\ b_5$; $c_6\ b_6$ is also the annual payment which in 5 years with interest will amount to the depreciated value, $b_5\ x_5$. Now, the Committee argues, assuming that the depreciated value must be taken, that the company should be allowed to earn a fair return on $b_5\ x_5$ plus an annual depreciation charge of $c_6\ b_6$, which is the same thing as a fair return on $b_5\ x_5$ plus sinking-fund interest on $a_5\ b_5$ plus the depreciation charge, ab. If, therefore, the rate of return on the property is

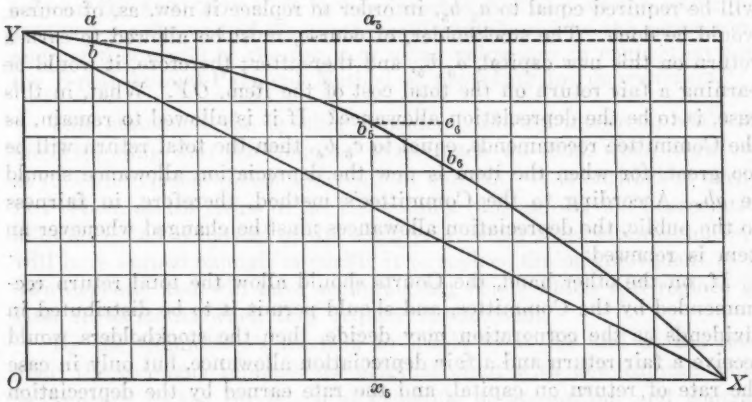

FIG. 8.

equal to the sinking-fund interest, this is the same thing as a fair return on OY plus a depreciation charge, ab. If, however, as must be assumed the fact, the sinking-fund interest is less than a fair return on the investment, then the Committee's method does not allow a fair return on the original property plus a proper depreciation charge.

If, therefore, a concern built to-day, and costing OY, is appraised 5 years from now, and if, on account of the original records being lost, or for any other reason, the cost-of-reproduction method is used, it will result in not allowing a fair return to the investor on his investment. It must be reiterated that though the rate-payers have contributed the sums which go into the depreciation fund, the stockholder has not received them; the company has received them, but it is obliged to keep them available for a specified purpose, namely, for reproducing the property when it is worn out. The statement of the

Mr. Swain.

funds cannot be invested in the plant, and the rate of return on the sinking fund would be less than that received from the investment. Indeed, inasmuch as the sinking fund must be assumed to be invested safely above all things, there seems to be no reason for assuming a greater rate of interest on it than the company receives for its cash, or the rate of interest for time loans, which, in general, would be less than a fair return on the investment. In this case, the Committee's method, as shown by Column 7 of the table on page 34 of the report gives a smaller return, except in the first year, than is fair. It results, therefore, in confiscation.

The object of the Committee, however, is perfectly clear and quite praiseworthy. It assumes that two things have been finally and irrevocably settled by the Courts:

First.—That the cost of reproduction-new-less-depreciation must be used as a basis;

Second.—That the mistakes of the company in the past, in not charging rates sufficient to provide a fair return plus a depreciation allowance, cannot now be rectified.

These two findings are justified in the decision of the Supreme Court in the Knoxville case. It must be remembered, however, that the Courts, being human institutions, are subject to error; that every Court has had its decision reversed probably more than once; and that the Supreme Court of the United States has reversed its own position in a number of instances.

Much is said, in discussing this subject, as to respect for the Courts. The speaker believes that there is no one who has greater respect for them than he, but it is very important to understand clearly what respect for the Courts implies. It certainly does not imply agreeing in all cases with their decisions, or even accepting them without argument, if we believe them wrong. Judges, like those who are judged in this world, are human, and it would be less respectful to attribute to them superhuman attributes by assuming them to be always correct and infallible, than to admit their fallibility. Proper respect for the Courts means that we should believe our judges to be honest, faithful, disinterested men, honestly striving to administer justice, and that we should accept their verdicts when rendered, if we have to and are obliged to act on them; but that does not prevent us from fighting with all our might and main to convince them that they are wrong, if we believe such to be the case. The present subject is in the making, and it is quite possible, if not probable, that the Supreme Court may reverse its finding with reference to the facts referred to. Assuming those findings to be correct, however, the Committee pursues a perfectly consistent course. This may be illustrated graphically:

Mr. Swain.

In Fig. 8 let OY be the first cost of a piece of property, and OX its life, say, 10 years. The curve of the sinking-fund depreciation is shown by the curve, YX. ab is the annual payment which in 10 years will amount with interest to the original cost, or the assumed cost of reproduction. At the end of 5 years, five annual payments have been made, which, with interest, amount to $a_5\ b_5$, leaving $b_5\ x_5$ as the assumed depreciated value; $c_6\ b_6$ is equal to ab plus the interest for a year on $a_5\ b_5$; $c_6\ b_6$ is also the annual payment which in 5 years with interest will amount to the depreciated value, $b_5\ x_5$. Now, the Committee argues, assuming that the depreciated value must be taken, that the company should be allowed to earn a fair return on $b_5\ x_5$ plus an annual depreciation charge of $c_6\ b_6$, which is the same thing as a fair return on $b_5\ x_5$ plus sinking-fund interest on $a_5\ b_5$ plus the depreciation charge, ab. If, therefore, the rate of return on the property is

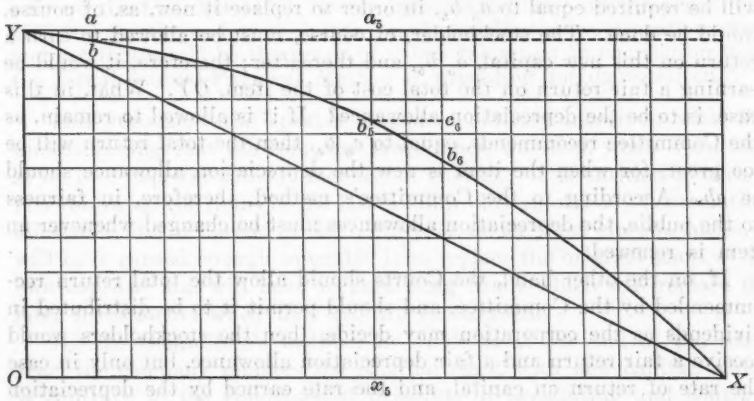

FIG. 8.

equal to the sinking-fund interest, this is the same thing as a fair return on OY plus a depreciation charge, ab. If, however, as must be assumed the fact, the sinking-fund interest is less than a fair return on the investment, then the Committee's method does not allow a fair return on the original property plus a proper depreciation charge.

If, therefore, a concern built to-day, and costing OY, is appraised 5 years from now, and if, on account of the original records being lost, or for any other reason, the cost-of-reproduction method is used, it will result in not allowing a fair return to the investor on his investment. It must be reiterated that though the rate-payers have contributed the sums which go into the depreciation fund, the stockholder has not received them; the company has received them, but it is obliged to keep them available for a specified purpose, namely, for reproducing the property when it is worn out. The statement of the

Mr. Swain.

Committee that inasmuch as the sum, $a_5\ b_5$, has been returned by the rate-payers, the company is not entitled to receive a further return on this property, is an evident fallacy, for though $a_5\ b_5$ may represent what has been paid by the rate-payers, with interest, it has not gone to the stockholder, and interest on this sum is not entered in the capital account, but in the reserve account.

Moreover, even supposing the Committee is justified in believing, or hoping, that the Courts would allow a fair return on $b_5\ x_5$ plus a depreciation allowance, $c_6\ b_6$, is it not equally probable that the Courts will require the latter to be held in reserve and not distributed as dividends? In this case the property of the stockholder is confiscated.

Moreover, if a depreciation allowance of $c_6\ b_6$ is permitted, this will allow the replacement of the property when worn out, at the point, X, only its depreciated condition, represented by $b_5\ x_5$ and new capital will be required equal to $a_5\ b_5$, in order to replace it new, as, of course, would be done. The stockholder, of course, must be allowed to earn a return on this new capital, $a_5\ b_5$, and thereafter; therefore, it would be earning a fair return on the total cost of the item, OY. What, in this case, is to be the depreciation allowance? If it is allowed to remain, as the Committee recommends, equal to $c_6\ b_6$, then the total return will be too great, for when the item is new the depreciation allowance should be ab. According to the Committee's method, therefore, in fairness to the public, the depreciation allowances must be changed whenever an item is renewed.

If, on the other hand, the Courts should allow the total return recommended by the Committee, and should permit it to be distributed in dividends as the corporation may decide, then the stockholders would receive a fair return and a fair depreciation allowance, but only in case the rate of return on capital, and the rate earned by the depreciation fund, were identical; if the latter were less than the former, as must be assumed, the property of the stockholder would be confiscated, for it would not receive a fair return.

All this uncertainty and complication will be avoided by allowing a fair return on the cost-of-reproduction-new, and a fair depreciation allowance on this same sum (namely, ab), which will renew the item, if new, in the term of its life, independent of its age when the valuation is made.

It seems reasonable to assume that the Courts will finally see the truth of this, if we insist upon it, and make it as clear as we can.

It is true that the method recommended by the Committee is fairer to the corporation than that which has often been followed. It is much fairer for the corporation to be allowed (referring to Fig. 8) a fair return on $b_5\ x_5$ plus a depreciation allowance of $c_6\ b_6$ than to be allowed only a fair return on $b_5\ x_5$ plus a depreciation allowance of ab. But the speaker maintains that the investor is entitled to

a fair return on OY plus a depreciation allowance, ab. He believes that the Committee loses sight of the fact that the question is not that of following a piece of property throughout its life, but of jumping in at some intermediate period, as at x_5, with no knowledge of original cost, and determining at that time the value on which fair returns should be allowed. Mr. Swain.

The Committee, in its illustrations in the Addendum, assumes that in each year precisely the depreciation allowances are invested—no more and no less—in extension of the plant. Refer, for instance, to Tables 5 and 6. Table 5 represents the sinking-fund depreciation invested in the plant, and the value-new is given in the last column. The Committee says:

"It would be grossly unjust to the rate-payers to permit the owner of the property, under the conditions presented, to earn dividends, not only on the $100 000 which he has invested, but also on the additional $177 609 [at the end of the ninth year] contributed by the rate-payers, and yet this would be the result of using value new in connection with the Equal-Annual-Payment Method of providing for depreciation."

This statement the speaker considers entirely incorrect, with the understanding that the company must renew an item, when worn out, at its own expense without increase of capital. It is entitled to earn a fair return on the items in the last column plus an original depreciation allowance, and at the end of the tenth year, under these circumstances, it will have earned enough to enable it to replace the original plant at its own expense, and will have accumulating funds which will replace the later investments when they require replacement.

By the Committee's method, in Table 6, at the end of the tenth year, the company replaces the original plant with new capital, which is contrary to the fundamental principle of accounting and contrary to the rules laid down by the Interstate Commerce Commission, and indeed contrary to all sound principles of financial management. Of course, it is easy to see what the Committee has done. It has assumed that the original plant has been exchanged for the new plant which has been built from the depreciation allowances, and that instead of selling these additions and putting the money into replacement of the original plant, it simply invests its new capital in renewal. This illustrates, however, in the speaker's opinion, the confusion which exists in the report; the illustrations are ideal, not real; theoretical, not practical. No concern would be able to invest each year, beginning with the second year, precisely the depreciation earnings in extensions. Indeed, it is illogical and misleading to confuse the question by assuming that depreciation earnings are invested in the plant. So far as the rate-payer is concerned, it makes no difference what is done with the depreciation earnings. If we can decide correctly how to treat the

Mr. Swain.

original plant, we shall then know how to treat any additions to that plant. The original plant should be kept separate in our consideration, and the fundamental principle must be maintained that it must be renewed by the company, when worn out, at its own expense. The Committee's method of treating the subject is misleading and confusing in this respect.

The speaker has taken Table 5 and extended it, showing what the result would be, if, as he maintains, the company should be allowed to earn a fair return on the value new plus a depreciation allowance. The result shows that at the end of 10 years there is an amount available which will be sufficient to replace the original plant without new capital; it also shows additional sums equal to the proper depreciation allowances necessary to replace the extensions which have been paid for from depreciation earnings.

Much has been said about the depreciation fund, and the question now arises, how large a fund is necessary in the case of an ordinary public service corporation. Such a corporation, after a few years of operation, settles into what may be called a state of financial stable equilibrium. Just about the same sum will be needed each year for renewals, and the only depreciation fund, or reserve, that is necessary is one which is large enough to take care of the yearly inequalities in these renewals. A railroad company, for instance, with hundreds of thousands of ties, thousands of tons of rails, thousands of bridges, stations, cars, locomotives, and other items of property, requires practically a nearly uniform sum each year for maintenance and renewals. In one year it may have to renew more bridges than usual; the next year it may have to renew less, and so with the other items. A comparatively small sum is all that is needed as a depreciation fund or reserve, and the larger the property—that is to say, the more numerous the individual items—the less the fund will have to be. This fund is simply in the nature of a reservoir to balance annual inequalities, exactly as the reservoir for the water supply of a city is required to balance the unequal draft at different hours of the day or in different months of the year. The more uniform the draft and supply, the smaller the reservoir may be. In other words, the depreciation allowances set aside for any given item of property in any given year are at once paid out to renew other items which require renewal in that year.

The speaker wishes also to call attention to another source of confusion in the report of the Committee, and one which is also to be found in many reports and decisions. It arises from confusing two meanings of the word "depreciation". Properly understood, depreciation means a loss of value due to wear and use, or to approaching obsolescence. This is the kind of depreciation that we have

Mr. Swain.

been considering. The word is often used, however, to mean also the lessening of value due to the fact that a given piece of property might be produced to-day at a less cost than it could be produced for when new. This is an entirely different thing, and the same term should not be used for it.

When it is claimed that the cost of reproduction new should be used as a basis for rates, the reply is often made by those who have not considered this distinction: "That cannot be correct; you allow the appreciation of land because it has increased in value; why should you not allow the depreciation of those elements which have decreased in value; one is the opposite of the other; you should allow both or neither."

This argument is fallacious, as will clearly be seen by considering the foregoing distinction. The reason we allow the appreciation of land is because we are using the cost-of-reproduction method, and, in using that method, we do allow for "depreciation of things which have depreciated". That is to say, every element of property which costs less to produce to-day than it did originally we put in the inventory at its cost to reproduce to-day, just as we put in the land at its cost to reproduce to-day. Items of property which cost more to reproduce to-day than they did originally we put in at their present cost; items which cost less to reproduce to-day than they did originally we put in also at their present cost; we make no difference. The question of depreciation due to wear has nothing to do with this; it is an entirely different one. Instances of this fallacy will be found in the Committee's report, and also, for instance, in the decision quoted by the Committee on page 51, which, instead of being clear, as the Committee states, the speaker considers to be quite confused in its reasoning. For instance, on page 50, the Committee says:

"The Courts have recognized that the corporation is entitled to earn from the public the sum necessary to offset the depreciation in the value of its structural property; similarly, the public is entitled to receive from the corporation due recognition of the increase in value of those portions of its property which appreciate in value. The principle involved in the two cases is the same, and there is no reason to think that its application to both would not be supported by the higher Courts."

The speaker respectfully contends that the principle involved in these two cases is not the same, but is entirely different.

The question of depreciation due to wear, then, is not to be set in contrast with the appreciation of land, and it is this depreciation which we are considering. If we consider the cost-of-reproduction method, we must put in every element, land included, at the fair cost of reproducing it to-day, whether it is greater or less than its original cost.

Mr. Swain.

In view, therefore, of the arguments adduced, there is no question in the speaker's mind that in valuation for rate purposes the undepreciated value should be taken, unless we are ready to admit that the cost-of-reproduction-new is not to be taken as a figure which replaces the original cost, which cannot be ascertained. If, however, we assume that the reproduction value is not to be taken in place of the original cost, then we find ourselves in the logical inconsistency, when we use the reproduction method, of using a method which does not give the same results as an admittedly correct one (namely, the original cost) in cases where both are applicable.

TABLE 24.

(1) Year of operation.	(2) Percentage on investment earned for distribution to investors and for replacements and renewals.	(3) Percentage paid to investors.	(4) Percentage remaining for replacements and renewals.	(5) Depreciation in percentage.
1st	5.00	5.00	0.00	4
2d	5.75	5.75	0.00	4
3d	6.50	6.50	0.00	4
4th	7.25	7.25	0.00	4
5th	8.00	8.00	0.00	4
6th	8.80	8.00	0.80	4
7th	9.60	8.00	1.60	4
8th	10.40	8.00	2.40	4
9th	11.20	8.00	3.20	4
10th	12.00	8.00	4.00	4
Total for 10-year period	84.50	72.50	12.00	40
Average for 10-year period	8.45	7.25	1.20	4

Table 24 will make clear the fact that to take the cost-of-reproduction method, using the value-new-less-depreciation, may, in some cases, mean confiscation. Suppose, for instance, that a public utility property is constructed and put into operation—let us say, an interurban street railway. Suppose that all the money is expended properly and that the road competes with a steam road and charges rates, say, 10% less than the latter, in order to attract business. Suppose there is no need of expenditure for renewals for the first 10 years, after which renewals begin, and soon attain a state of stable equilibrium. Suppose that the percentage earned on the investment which is available for distribution to investors and for replacements and renewals—that is to say, the amount earned above operating expenses and taxes—is as shown in Column 2, varying from 5% in the first year to 12% in the tenth and subsequent years. Suppose that investors receive the percentage in Column 3, varying from 5% in the first year

up to 8% in the fifth year and in each year thereafter. Then the percentage remaining for replacements and renewals will be as shown in Column 4, being zero for the first 5 years, and increasing to 4% in the tenth year and thereafter, the total accumulation in 10 years being 12% on the capital. Suppose that the depreciation is calculated by the straight-line method, taking a life of 25 years, or 4% per annum, making 40% in the 10 years. Mr. Swain.

This property, then, at the end of the 10 years, is earning 12% and gives every indication of continuing to earn that amount, of which 8% is paid to the investors and 4% remains for replacements and renewals, in addition to the fund of 12% which can be drawn on for the same purpose. The property is successful, and although the original cost was $1 000 000, its stock sells for about 120; that is to say, is bought and sold between investors on the basis of $1 200 000.

Now, suppose that, for some reason or other, the original records have been destroyed, perhaps by fire, and that an appraisal is to be made at the end of the tenth year. The cost-of-reproduction method is used and shows a cost-of-reproduction-new equal to $1 000 000; but the commission says we must take the depreciated value, and the depreciation is about 40%, so that as a basis for earnings, the value of the property is only $600 000. To this we may add the 12% in the renewal fund, or $120 000, making a total of $720 000. A similar result is reached if we use sinking-fund depreciation. The original stock paid 8% and called for a distribution of $80 000 annually. If 8% is now only to be allowed on $720 000, it will call for $57 600 annually, or 5.76% on the par value.

Under these circumstances, the value of the stock in the market will drop from 120 to perhaps 80 or 90, and if there is danger that some public authority will take the property on the basis of a value of $720 000, the stock may drop to 72, or even lower. In other words, the value made on the basis of cost-of-reproduction-new-less-depreciation, would confiscate the property of the stockholders, which was selling in the markets at $1 200 000 and justified that value, and now becomes worth only about $800 000, or perhaps less. If this is not confiscation, then the speaker does not know what confiscation is.

This issue must be faced. The Committee, in the table on page 34 of the report, shows a progressively decreasing return on the value of the property, and, on page 49, it says:

"It is true that of the return on a given item of property, the part applicable to dividends becomes less as the property grows older, but this is as it should be; a part of the capital invested in that item has been returned and has either been invested in additions or replacements, or temporarily in a depreciation fund, so that the whole of the original investment is at all times earning returns applicable to dividends".

Mr. Swain.

As has been already demonstrated, it is only when the rate of return on the property, and the rate of return on the depreciation fund, however used, are the same, and if the depreciation allowances may be divided, in part, among the stockholders as dividends, that justice will be done; otherwise, there will be confiscation.

This report will be understood to mean, the speaker believes, that dividends should decrease progressively, or that, if a valuation is made of an admittedly successful and honestly financed concern, like the one used in the previous illustration, then dividends must be reduced on the basis of that valuation. Does the American Society of Civil Engineers, or a Special Committee of the American Society of Civil Engineers, wish to advocate such a procedure? And if so, for what reason? Merely because the Courts may have made mistakes in the past; and to conform to an ideal and unreal point of view taken by the Committee. This report will postpone the day when public service commissions, Courts, and the public will perceive that a continuing concern, honestly serving the public at fair rates, is entitled to dividends equal to a fair return on the full amount of the investment; and by assuming, as a part of the argument, that all depreciation reserves are invested in extensions, it will obscure the fundamental principle that property which wears out should be replaced by the company in kind at its own expense.

If thus interpreted, it may do great injury to public utility companies, and so to the public at large.

There is one quotation which the speaker wishes to get into this discussion somehow, if Mr. Humphreys does not include it in his remarks. It is from a brief by Charles F. Mathewson, of the New York Bar, in the case of the Kings County Lighting Company *vs.* The Public Service Commission, and Mr. Humphreys says it is the most logical statement he has read. Mr. Mathewson says:

"The proposition [to deduct 'accrued depreciation' in valuing plants in rate-making] is so absurd on its face that it hardly needs discussion to show its fallacy. Why, aside from the question of 'confiscation', should consumers, for exactly the same service, equally efficiently rendered, expect to pay less in the sixth year than in the first year, merely because some items of plant will (viewed at the sixth year) require replacement at a date in the future then nearer than such date was at the beginning of operation? As well might it be claimed, to repeat a homely illustration, that a farmer should regulate the price of the eggs which he sells, by the age of the hen which lays them—reducing the price of the product as the hen gets on in years. The reason he does not is that the service efficiency and operating value of the hen, as evidenced by the quality of the eggs which she lays, are not impaired by the fact that her life is advancing. That advancement may concern the farmer and possibly concerns the hen; but it in no manner affects the value of the eggs to the consumer, or justifies

Mr. Swain.

him in demanding them at a lower price than he paid at an earlier period of her life. The consumer of the eggs must expect to pay a sufficient price to afford a return to the farmer on his total investment in the hen during her life, *plus* enough more to enable the farmer on her death to replace her, and thus keep his investment unimpaired. A farmer could hardly be expected to invest in hens for the purpose of supplying the public with eggs, if for a portion of their life he was to receive a return on only a third or a half of his investment; and any such rule would simply compel the public to go without eggs until the regulating power (if such there were) saw fit to revise its reasoning. There is absolutely no difference in the economic principles applicable to the operation of a gas plant and the operation of a hennery, so far as concerns right to return on capital; and what is absurd in one case is equally absurd in the other. The fact that the rate of return in the one case is subject to reasonable regulation, and not in the other case, has no bearing on the main proposition."

Mr. Mathewson is here arguing against the proposal to allow the stockholder only a fair return on cost of reproduction-new-less-depreciation.

The speaker wishes to say one word in regard to Mr. Snow's statement, in order not to be misunderstood. The speaker did not say that the reserve funds should not be invested in the property, but did maintain, and still maintains, that it confuses the main question to assume that they are necessarily going to be invested in the property. They need not be, and in some properties there is no expansion for many years. It confuses the question to assume that they are going to be thus invested. They must be invested so as to bring a return, and the only obligation the company is under is to replace every element, as it wears out, in kind, at its own expense. The speaker wishes to be distinctly understood that he did not say that it was an improper use to invest the reserve funds in the property; and he also called attention to the fact that, in most public utility corporations, such as railroads and street surface railways, a small fund will provide for all necessary contingencies; that is, for the variation in the renewals from year to year, only a small fund is required, and that is all that need be held.

Mr. Ledoux.

J. W. Ledoux, M. Am. Soc. C. E. (by letter).—In regard to the valuation of utilities for the purpose of rate-making, it would be desirable if engineers could agree on general rules which could be followed in all cases with the least injustice both to the owners of these utilities and the public.

In these questions most people look to Court decisions for their authority, but the Courts have not settled the matter definitely, and they, as well as those versed in the law, cannot be expected to have

Mr. Ledoux.

the special training to handle this particular problem as well as technically trained and experienced engineers free from bias.

The writer is of the opinion that the members of the Engineering Profession are freer from injustice than those of most other professions. Unfortunately, however, partisanship does exist, and it is common to find municipalities or private corporations looking for engineers who know how to, and will, make a strong plea for their side of the case. This phase, in an exaggerated form, was illustrated by a prominent engineer who was heard to say recently that "If a consulting engineer, in his public testimony, is known to have given a corporation fair treatment, his 'goose is cooked' forever afterward as far as municipal employment is concerned". This condition tends toward shiftiness and ambiguity in the discussions of some of those whose standard of justice is subservient to their own pecuniary interest.

There are comparatively few points on which engineers should differ, and it is believed that they would be in perfect accord in all the principles if they were agreed as to the premises.

This discussion is written from the standpoint of a water-works plant, and is based on what the writer considers, at the present moment and after careful reflection, to be abstract principles of justice. These conclusions were reached after the successive abandonment of several materially different opinions which, at the time, were held with more or less assurance. He realizes that as now drawn they are not strictly in accord with some Court decisions which necessarily must be the gospel, but, in their final analysis, they would be based on the concensus of opinion as to what constitutes fair dealing.

If a public utility were being taken over by a municipality by the process of condemnation, the rates and revenue being settled, it is evident that the value of the utility should be paid. If, however, a public commission has in hand the establishment of rates for a utility, the question of condemnation being non-existent, then the cost of the utility should be determined, in order to find the proper and just fixed charges. In the case of condemnation, if the municipality has the right to establish its own works, and the present plant is adequate, the cost of reproduction less depreciation plus the value of the established revenue should be the criterion. In the case of establishing rates, the cost of the existing plant should be the criterion—not necessarily what it cost the owners, but what is reasonable and proper under the circumstances in which the existing plant was built and developed. Where there is doubt, the recorded book cost should be the guide.

As to the items making up this cost, there should not be material difference between experienced and intelligent opinion. Those things which cannot generally be avoided in average or ordinary practice should be allowed—the cost of preliminary engineering; legal, finan-

Mr. Ledoux.

cial, and other expert reports; cost of promotion, organization, surveys, designs, land, rights of way, water rights, title examinations, and management, are some of the items which come in before any work is done. Then there is the cost of construction; liability and other insurance; interest during construction; architectural, chemical, legal, engineering, and other expert fees and commissions; cost of lawsuits; most of which items and more are practically certain to occur. There should be added, also, an item for contingencies to cover things which cannot be foreseen, but which, in some form or other, are sure to occur, such, for instance, as weather difficulties, errors, accidents to plant or materials of construction, delays and extra expense due to various causes, such as non-arrival of material, injunctions, obtaining of permits, changes of grade, caving, settling of embankments and foundations, defective dams or reservoirs, failure of sub-contractor, strikes, and many other things which cannot be specifically foreseen, but which should be allowed for in a general percentage based on experience. There are also the items of financing, underwriting, and general contractor's profit.

Then when the works are finished and capable of supplying service to the community, it generally takes 10 years or more before enough contracts can be obtained to pay current expenses. During this period of waiting, which is common to the majority of plants, when, also, there may be further improvements, construction, and extensions, which, of course, must be allowed for, the owners would have to pay out much more than they receive, and this deficiency of receipts is a necessary item to figure in the development cost of the plant.

It is often held that the valuation of a plant should be the same whether the question of rates or purchase be considered. Theoretically, the position is unsound, for in the case of rates we have a property which properly represents a given investment, on the basis of which rates should be established to yield a revenue profitable to the owners. In the case of purchase there is a given revenue with a given property to determine its value. This revenue may make the property a losing or a profitable venture, and, manifestly, the value of the property for purchase is directly influenced by this fact.

The proposition that the cost instead of the value should be taken in establishing rates may not be accepted immediately, on the ground that, value being established regardless of cost, if any other basis be taken, the property is subjected either to inflation or confiscation. However, from the moment it is decreed that the State has the right to fix the rates of a utility, its power to fix value follows as an inevitable consequence.

It will be generally conceded that the State should recognize as just such revenues as would pay the owners of a utility a reasonable

Mr. Ledoux.

return on their investment, but here we are confronted with another difficulty. The investment of the present owners of the utility may have been based on value instead of cost. They may have paid for the utility, by reason of its existing or prospective net revenue, more or less than the cost of the actual items entering into the creation of the property. If, however, these existing net revenues were in all cases just to the utility and the public, there would be no reason for State supervision of rates.

It may be assumed, therefore, that the State would look on such rates as unjust, that would yield an undue return on the reasonable cost of the existing utility. As illustrative, a municipality invites a concern to establish a water-works, the character of which and the water supply being definitely specified. The necessary investment and the rates are agreed on. After some years, the municipality decides to build its own works, possibly at less cost, and, being freed from such expenses as taxes, licenses, permits, etc., the cost of operation will thereby be reduced. Prior to this decision, the net revenues paid a reasonable return on the investment, but, fearing competition and a deficiency of revenue, the original company sold its property to a new company for half the cost. Then a rate-making commission is established, and is called on to determine rates. As an opposite case, a water-works is established in the same manner. The growth and density of population and the net revenues became so great, coupled with the fact that they own the only available water supply, that the original owners are enabled to sell to a new company for double the amount of their investment; after which the rate-making commission is called in to establish new rates. In both these and all such cases it would seem that the criterion should be the proper and necessary investment to produce the actual property, regardless of past trading and stock jobbery.

As a general proposition, where there is no contract, it would be desirable and equitable if the value of all public utilities were identical with the proper and necessary investment, so, if the rate-making commission is presented with a case in which the rates are so high or so low as to produce revenues which make the value different from the cost, should it not readjust these rates to the proper basis? The existence of iniquity and the investment therein does not establish the right to its continuance.

In the abstract, value varies as revenue, which varies as rates, which should vary as cost, and, consequently, value should vary as cost; but if the commission does not have the right to establish rates, then value varies as revenue, revenue varies as rates; but rates depend on "what the traffic will bear", and not on cost; therefore, in this case, the cost and value have no direct relation.

Mr. Ledoux.

Heretofore, in cases of condemnation by the municipality, or arbitration of the value of the utility, it has been held with justification that an important element of valuation was "going value", which represented what a purchaser could afford to pay for a given plant with revenue, above what the same plant was worth where the purchaser was obliged to wait for the acquisition of that revenue. In such cases this item is truly an element of value, but, in rate cases, it cannot be considered in the same way, because the rates have not yet been established on which to figure the present worth of the deficiencies of revenue according to an assumed rate of revenue increase. For rate purposes, it would be more proper to call this item "development cost", which may be defined as the necessary net outlay over and above the cost of the physical plant up to the time it is earning a reasonable return on the total investment. The practical outcome of this, however, is the same as that of "going value".

In rate cases, if one must determine this item by calculation, it will be necessary to cut and try. First, assume this item, a revenue, and a rate of increase. From the fixed charges, operating expenses, and assumed revenues, the present worth of the deficiencies of revenue can be calculated. If that does not agree with the assumed development cost, try another value, until finally there is an agreement. If the assumed revenue is more or less than enough to pay a reasonable return on the calculated total cost, a new value for revenue must be assumed, using the same rate of increase as before. Proceed in this manner until the calculated results agree with the assumption; after which, one may be as close to what it ought to be as though he had guessed at it in the beginning.

In many lines of investigation, the snap judgment of a person having broad experience is more reliable than the most abstruse calculation.

Some argue (and generally with justification) that this element of cost should be based on the actual experience of the plant under consideration, but this plant might be grossly mismanaged, more than ordinarily well managed, or the personnel of the operating force may antagonize the patrons; at any rate, it does not seem wholly proper to base cost on the reluctance or alacrity of the consumers to patronize the utility.

If the foregoing reasoning is sound, then the cost to reproduce the given plant will be taken as the basis on which to determine rates, and not the present rates as the basis of determining value, and, as a consequence, new rates.

Now, if the cost, or what is the same thing, the necessary investment, is the proper basis for the commission to adopt in establishing rates, how is this to be determined?

Mr. Ledoux.

There is justification for a method which will wipe out past history entirely, take the plant just as it exists, and calculate what such a plant would reasonably cost to construct and develop up to the present. This method would depend entirely on the appraiser's judgment, and this is where such a committee as that of the American Society of Civil Engineers could formulate certain rules of practice which would be of great aid to the appraiser, and which might become a recognized standard by the commissions and the Courts. These rules of practice should be determined, it appears to the writer, by studying carefully the history of twenty or more representative plants in towns having populations of from 2 000 to 1 000 000, and using the data thus obtained for calculating the uncertain and difficult elements of the plant under consideration. The cost of reproduction of the physical plant is neither difficult nor uncertain, but the estimate of the cost of development is the element that should be derived by the method suggested, and, in fact, the Committee might go farther and formulate some scheme such as the following:

First, estimate the cost of the physical plant and property as it exists, taking average prices which have been current for the past 10 years. To the sum thus obtained should be added certain percentages for each of the following items: Promotion and organization expenses, engineering, financing, legal expense and lawsuits, contingencies, and general contractor's profit, and from this total sum should be deducted the cost of constructions which are obsolete or of no value in the plant. The remainder should be the cost to reproduce the physical plant as it stands; there should also be added a general percentage for errors and constructions which are useless, but which are practically sure to occur and impossible to avoid in the majority of plants. Then there should be added a general uniform percentage of from 15 to 40% for development, and this percentage should be determined from the analyses of the twenty or more water-works referred to.

When these percentages are once determined and recognized as reasonable, this method would seem to be the most satisfactory that can be devised for arriving at the proper cost, and in a majority of cases it will be fair both to the owner of the utility and the people. After the cost is once derived in this way, it only remains for the commission to establish such rates as will produce a revenue sufficient to pay all operating expenses, fixed charges, depreciation, and a reasonable return to the owners of the utility.

Many engineers would object to this method on account of the arbitrary fixing of certain percentages to allow for uncertain elements of cost, but, no matter what allowances are made, they must necessarily be based largely on speculation, and it is an advantage, where speculation cannot be avoided, for all engineers to speculate uniformly, for then we will not be confronted with cases like one which came

to the writer's knowledge a few weeks ago, where, in the valuation of a water plant for establishing rates, three experienced engineers estimated the "going value"; two made it some $30 000 odd, and the third more than $130 000. Mr. Ledoux.

At first sight this method would appear to give the recently established water company an undue advantage by reason of its not having incurred the expenses of development belonging to one established for more than 10 years, but these expenses are sure to occur later, and the rates should be such as would yield the desired revenue when the consumers are connected up at the end of the development period.

The subject is one of great difficulty, and no method can be devised which will not in some exceptional cases be apparently unsatisfactory, but, until some recognized method is adopted fair to the utility, investors will not be willing to embark in propositions of this kind, and the people will be the ultimate losers.

It will be observed that in this discussion no deduction has been made for accrued depreciation. From the moment a plant is built, depreciation, an insidious enemy, begins to rob it of its substance and carries away every year a definite portion of its value. If the owners of the plant were responsible for the robbery, they should not receive credit in valuation for the property thus abstracted, as, for instance, if they sold every year a definite portion of the plant and kept the proceeds for their personal use. On the other hand, if the public, or people, living along the lines, for whose benefit or use the utility was constructed, were responsible for this annual abstraction, then the owners of the plant should be reimbursed by the people. When the plant was built, however, both parties recognized the existence of this enemy and the extent to which his maraudings would inevitably reduce the value of the property each year, and the necessity of maintaining by replacement as required the property thus lost. The money to pay for the cost of these replacements can come from only two sources: the owners of the utility or the people. If it comes from the owners, unless they be the people, there is no return for the money thus expended. Unless the utility be a philanthropy, the owners must be reimbursed at least for all legitimate and unavoidable expenditures, for even then the undertaking is profitless. This reimbursement can only come from the revenues produced by the rates charged the people for the service rendered. As this abstraction of value by depreciation neither reduces the amount of the investment, nor inures to the benefit of the owners, therefore, in valuation for rates, no deduction should be made from the proper cost of the property for accrued depreciation.

It will be asked, how is one to insure that the owners of the plant will provide out of the revenues thus produced an inviolable fund

Mr. Ledoux.

for depreciation, instead of pocketing this allowance or paying it out in dividends, and letting the plant gradually go to destruction?

If the revenues produced from the rates established by the commission are large enough to pay operating expenses, taxes, interest, depreciation, and profit on the legitimate original cost of the works, and the owners of the plant do not invest this depreciation fund in the plant, it has lost just so much value or investment cost, which has gone to make the profits unduly large. Consequently, an equivalent deduction in cost should be made when the commission again establishes rates.

The same principle should apply the first time if it is found that the previous revenues have been high enough to pay all expenses, profit, and depreciation, while the plant has been allowed to depreciate with nothing to show for a restoration fund.

For purchase, the case is entirely different, depending on the conditions outlined in the four following cases:

Case 1.—The city condemns, the rates being fixed;

Case 2.—The city and owners of the utility mutually agree to an arbitration, the rates being fixed;

Case 3.—The commission establishes the value of the plant at which it will be taken over by the city, the rates being under the control of the commission;

Case 4.—The city purchases by mutual barter, the rates being fixed.

In each of the first three cases, according to the writer's judgment, depreciation should not be deducted unless the company has been earning sufficient to pay all expenses, including depreciation and a reasonable profit, and no restoration fund exists.

In Case 4 depreciation would naturally be deducted, at least by the representatives of the municipality.

The question of street pavements also leads to confusion of thought: If the works were built when no pavements existed, and these were afterward constructed by the city, should the rates be increased thereby, and, in case of purchase or condemnation, should these pavements be an element to increase the value of the utility? In the case of rates, the municipality has added a feature which increases the cost of maintenance and the final duplication of the piping system and, to that extent, the revenues and rates should be increased.

In case of purchase by barter, where the municipality has no right to condemn, pavements certainly add to the value of the utility on account of the greater cost to the municipality to duplicate the piping system. In case of condemnation by the municipality, or the establishment by the commission of a sale valuation, it is a serious question whether the commission should recognize as just an element of value that was created by and at the expense of the people.

ALBIN G. NICOLAYSEN, ASSOC. M. AM. SOC. C. E.—The proper treatment of depreciation is one of the most important questions in the valuation of public utilities. It is also one that has a tendency to become too involved to be followed easily if presented in general terms, and the speaker will not attempt to do this, although his conclusions were originally reached in that way. It is his intention to show how depreciation affects the value, for rate-making purposes, of the physical property owned by two imaginary companies operating under assumed simple conditions. In spite of the limitations of such a method, it will be found that the conclusions reached will apply quite generally, and, in addition, will be of material assistance when the examination is extended to companies operating under more general and more complicated conditions. Mr. Nicolaysen.

The first imaginary company which will be investigated, is assumed to operate a ferry-boat acquired at a cost of $100, and having a useful life of 10 years. If the company has no other investments, and if it is further assumed that it is entitled to earn 6% on its capital stock, and that the amount in the depreciation fund can be invested in such a way as to earn also 6% interest, then the rates should be high enough to return annually the sum of $13.587 over and above all operating and maintenance expenses, including insurance, taxes, etc., and are to be used only for depreciation and dividend payments.

If this is the case, the company is able to pay annually $6.00 to the stockholders and $7.587 to the depreciation fund. What the stockholders received was 6% on their investment, and what was paid to the depreciation fund, at the end of 10 years, under the assumed conditions, would amount to $100, enabling the stockholders to buy a new boat like the first one and continue operations under the original conditions, or to withdraw from the business with their capital unimpaired.

This shows that the combined dividend and depreciation payment in the assumed case, under fair management, should be $13.587 per year, and it is obvious that this amount is independent of the disposition made thereof. The company, if it so decided, could neglect to establish any depreciation fund, and pay out all the net earnings to the stockholders. This would not mean any increase in the return on the capital. The stockholders would receive 6% on their investment as before, and the amount paid in excess thereof, would be a repayment of capital, which in this way would be entirely returned at the end of the tenth year, when the boat would have no value.

Thus it appears that where replacements are paid for by the stockholders, the annual return on the physical property should be $(A + B)\%$ of its "value new", where A is the rate of interest on capital invested, and B is the rate of depreciation figured on the

Mr. Nicolaysen.

sinking-fund basis. This return is the same whether or not a depreciation fund is actually established, and should run undiminished through the assumed life of the property.

The correctness of this statement is confirmed by an examination of Tables 25 and 26. The value of the depreciation fund at the end of each year is shown in Table 25; where no depreciation fund is established, the investment of the stockholders is gradually reduced, as shown in Table 26, which gives the amount of the investment for each year.

TABLE 25.—SINKING-FUND DEPRECIATION. DEPRECIATION FUND CREATED.

Physical property costing $100 and having 10 years life. Annual net earnings $13.587: Stockholders receive 6%; remainder placed in depreciation fund and earning 6% per annum.

Year.	Capital invested.	Return to stockholders.	Depreciation Fund.		
			Payment at end of year.	Interest during year.	Value at end of year.
1	$100.00	$6.00	$7.587	$0.00	$7.59
2	100.00	6.00	7.587	0.45	15.63
3	100.60	6.00	7.587	0.93	24.15
4	100.00	6.00	7.587	1.45	33.19
5	100.00	6.00	7.587	1.99	42.77
6	100.00	6.00	7.587	2.56	52.92
7	100.00	6.00	7.587	3.17	63.68
8	100.00	6.00	7.587	3.82	75.09
9	100.00	6.00	7.587	4.50	87.18
10	100.00	6.00	7.587	5.23	100.00

TABLE 26.—SINKING-FUND DEPRECIATION. NO DEPRECIATION FUND CREATED.

Physical property costing $100 and having 10 years life. Annual net earnings $13.587, all paid out to stockholders; 6% considered as interest on investment, remainder as return of capital.

Year.	Investment at beginning of year.	Interest on investment.	Amount received by stockholders.	Investment reduced by:	Investment at end of year.
1	$100.00	$6.00	$13.587	$7.59	$92.41
2	92.41	5.55	13.587	8.04	84.37
3	84.37	5.07	13.587	8.52	75.85
4	75.85	4.55	13.587	9.04	66.81
5	66.81	4.01	13.587	9.58	57.23
6	57.23	3.44	13.587	10.15	47.08
7	47.08	2.83	13.587	10.76	36.32
8	36.32	2.18	13.587	11.41	24.91
9	24.91	1.50	13.587	12.09	12.82
10	12.82	0.77	13.587	12.82	0.00

Mr. Nicolaysen.

Although Tables 25 and 26 show clearly enough that the same amount is required to meet the fair claims of the stockholders, whether or not a depreciation fund is established, as a matter of policy such a fund should always be created by companies operating under conditions in any way similar to those assumed, as this is the only way in which such a company can be reasonably sure of the continuity of its enterprise and avoid the use of antiquated equipment.

The second imaginary company to be investigated is assumed to begin operations under exactly the same conditions as the company previously described, the difference between the two being that the first operates one boat only, and the second, through the opening of new routes, increase of business, etc., is enabled to add one new boat to its equipment at the end of each of the first 9 years, so that it begins its second year with two boats, of which one is new and the other 1 year old; its third year with three boats of which one is new, one is 1 year old and one is 2 years old, and at the beginning of the tenth year, it operates ten boats, one just acquired and good for 10 years' service, the next, 1 year old, and able to serve 9 years more, and so on down to the original boat which has given service for 9 years and has a remaining useful life of only 1 year.

Each of these boats, as in the case of the first company, is assumed to cost $100, to have a useful life of 10 years, and to earn, during every year of its operation, the sum of $13.587 net, available for depreciation and dividend payments.

It is further assumed that the limit of the profitable expansion is reached with the tenth year, and that, from then on, the number of boats operated remains stationary at ten, one new boat being purchased annually to replace the oldest boat in service, so that the equipment operated during the eleventh year, twelfth year, etc., will correspond exactly to that operated during the tenth year.

It has been shown in the case of the company operating one boat, that net operating earnings of $13.587 was sufficient to satisfy the fair claims of the stockholders, as it allowed the company to pay 6% dividends and create a depreciation fund which, at the end of 10 years, when the boat must be replaced, amounts to $100, the original investment.

Now it is evident that the fair return per boat is independent of the number of boats operated, so that ten times $13.587, or $135.87, must be a fair return for a company operating ten boats, and provides both for depreciation and dividend payments. In the case of the company now under consideration, the condition of the equipment in the tenth year is maintained indefinitely by the annual replacement of one boat at a cost of $100. This shows that the annual depreciation is $100 and that the portion of earnings from operation available

Mr. Nicolaysen.

for dividends is only $35.87, when the replacements are paid out of earnings. As the total "value new" of the equipment is $1 000, the interest on "value new", at 6%, is $60 in place of the $35.87 available for dividends; the latter amount is 6% of $597.80, which is thus the depreciated or present value on which interest should be figured.

The fact that earnings from operation are insufficient to provide both for the renewals of worn out boats and for a return at the assumed rate on "value new" of the physical property, does not prove that any portion of this value has been confiscated. It simply means that the total earnings include the return on the depreciation fund, created during the years when no renewals were required, and the combined earnings from operation and the depreciation fund—as shown in Table 27—will be found to be large enough to meet renewal charges and to yield the assumed return on the full "value new" of the equipment.

TABLE 27.—SINKING-FUND DEPRECIATION. DEPRECIATION FUND CREATED.

Physical property consists of boats costing $100 each and having 10 years life. One new boat purchased at the end of each year. Ten boats owned in the tenth and following years. Annual net earnings, $13.587 per boat operated. Stockholders pay for the first ten boats and receive 6% dividends. Remainder of earnings placed in depreciation fund that earns 6% per annum and pays the cost of renewals.

Year.	Capital invested.	Net operating earnings.	Return to stockholders.	Depreciation Fund.			
				Payment at end of year.	Interest during year.	Paid out for renewals.	Value at end of year.
1	$100.00	$13.587	$6.00	$7.587	$0.00	$0.00	$7.59
2	200.00	27.17	12.00	15.17	0.45	0.00	23.21
3	300.00	40.76	18.00	22.76	1.39	0.00	47.36
4	400.00	54.35	24.00	30.35	2.84	0.00	80.55
5	500.00	67.94	30.00	37.94	4.83	0.00	123.32
6	600.00	81.52	36.00	45.52	7.40	0.00	176.24
7	700.00	95.11	42.00	53.11	10.57	0.00	239.92
8	800.00	108.70	48.00	60.70	14.40	0.00	315.02
9	900.00	122.28	54.00	68.28	18.90	0.00	402.20
10	1 000.00	135.87	60.00	75.87	24.13	100.00	402.20
11	1 000.00	135.87	60.00	75.87	24.13	100.00	402.20
12	1 000.00	135.87	60.00	75.87	24.13	100.00	402.20

If no depreciation fund has been established during the development period, so that the company has no income other than that obtained from operation, then, of course, it is impossible to pay dividends at the assumed rate on more than the depreciated value, but the depreciation fund, in that case, is really invested in the equip-

ment, and the stockholders' equity in the same is, and has always been, equal to its depreciated value, a fact that is clearly shown in Table 28. Mr. Nicolaysen.

TABLE 28.—SINKING-FUND DEPRECIATION. NO DEPRECIATION FUND CREATED.

Physical property consists of boats costing $100 each, and having 10 years life. One new boat purchased at the end of each year. Ten boats owned in the tenth and following years. Annual net earnings, $13.587 per boat operated. Stockholders pay in new capital as required and receive 6% dividends. Remainder of earnings invested in new equipment.

Year.	Stockholders' investment at beginning of year.	Net Operating Earnings.			Additional investment by stockholders.	Stockholders' investment at end of year.
		Total.	Return to stockholders.	Invested in equipment.		
1	$100.00	$13.587	$6.00	$7.59	$92.41	$192.41
2	192.41	27.17	11.55	15.62	84.38	276.79
3	276.79	40.76	16.61	24.15	75.85	352.64
4	352.64	54.35	21.16	33.19	66.81	419.45
5	419.45	67.94	25.17	42.77	57.23	476.68
6	476.68	81.52	28.60	52.92	47.08	523.76
7	523.76	95.11	31.43	63.68	36.32	560.08
8	560.08	108.70	33.60	75.10	24.90	584.98
9	584.98	122.28	35.10	87.18	12.82	597.80
10	597.80	135.87	35.87	100.00	0.00	597.80
11	597.80	135.87	35.87	100.00	0.00	597.80
12	597.80	135.87	35.87	100.00	0.00	597.80

It is true that all the current earnings may have been paid out to the stockholders, and these may have paid in annually the full amount needed for additions, but this does not increase their investment any more than it would be decreased if all earnings should have been used for additions and no dividends paid, in which case the capital directly supplied by the stockholders falls short of their actual new investment by an amount equal to a fair return on the money previously invested.

In praxis, it will probably be found, in a majority of cases, that earnings during the first few years of a company's existence, are insufficient to provide for proper depreciation and dividend payments. In such cases the accumulated difference between what may be termed "fair earnings" and actual earnings, should normally be considered as development expenses and included in the intangible values. When this is done, it becomes unnecessary to assume as before that earnings from the very beginning shall be large enough to provide for a fair return on the value of the property. If early earnings are less than fair earnings, the company under consideration will later be entitled

Mr. Nicolaysen.

to a return both on its physical property and its development expenses, but that portion of the return which is based on the physical property will be exactly the same as that previously found.

The assumed rates of return on capital invested and on the depreciation fund were made identical, for the reason that normally it will be found to be both possible and desirable to invest the depreciation fund in additions and betterments. In view of the fact that the element of risk is largely eliminated from regulated utilities, the speaker is inclined to consider the assumed rate—6%—as fair, but it is not his intention to claim that it is necessarily the proper one, the object being primarily to fix a certain rate so that the tables could be calculated.

The claim is often made that if a depreciated plant is able to give as satisfactory service to the public as it did when new, it should also give the same return to the owners. This argument is entirely beyond the speaker's comprehension. If its correctness was recognized, it would seem that the ferry company previously considered could be made a very profitable investment by the simple expedient of buying old, but still serviceable, boats in place of new ones.

The speaker believes that the apparently very great differences between the companies here considered, and actually existing utilities, on investigation, will be found to be unessential.

In all cases the physical property may be divided into three classes: Class I is to include all items of property renewed out of capital; Class II comprises all groups of items which through annual renewals out of earnings are maintained indefinitely in approximately their present condition; and Class III contains all groups of items which eventually will be included in Class II, but which have not yet reached the stage where renewals make up for depreciation. Justice is done, both to the public and to the stockholders, when earnings are large enough to provide for depreciation payments on the sinking-fund basis on all property in Classes I and III, and to yield in addition a fair return to the stockholders on intangible values, on the "value new" of property in Classes I and III and on the depreciated value of property in Class II.

Mr. Lippincott.

J. B. LIPPINCOTT, M. AM. SOC. C. E. (by letter).—The report of this Committee is a most satisfactory and clear-cut discussion of this important subject. If the American Society of Civil Engineers can assist in standardizing methods for estimating reasonable rates for utilities in cities, it will be conferring a benefit both to the investor and to the public. The Committee states (page 21):

"The allowance for overhead charges has generally been substantially under-estimated by commissions and the Courts, as well as by engineers of limited practical experience in construction work. The

latter are prone to assume that unit prices bid by contractors or determined during the progress of the work by the inspector are fair measures of its final cost to the owner, but such is rarely the case." Mr. Lippincott.

In building an engineering work there are two classes of expenses: First, the expense of building the structure itself; and, second, the indirect expenses which are unavoidable and for which there is little to show after the work has been completed. Engineers who have been connected with large enterprises, and have carefully kept segregated cost accounts, are fully aware of the gravity of these indirect charges, whereas others, who have not had this experience, are apt to minimize them. It is to be regretted that so few such cost records are available. Estimates are prone to be below the actual cost. This is not due so much to failure to comprehend the cost of the structure itself, as to lack of realization of these unavoidable auxiliary, incidental, or general expenses. For the same reason, engineers or Courts who are evaluating properties are apt to consider only such structures as they may see on the ground. The worn-out tools and equipment, the monies paid for injuries to men and animals, or police protection, all have left on the ground no visible trace that may be appraised, yet they are clearly an expense incident to the construction.

Any official body whose duty it is to fix a rate for a public utility has a grave responsibility, not only to the public, but also to the investor. Justice requires that each shall be treated with fairness, and, usually, this is the intent. It is necessary for the proper development of a new country that great enterprises should be encouraged. Therefore, particularly if business profits, commensurate with the risk incurred, are not to be allowed in fixing the rates for utilities, and these institutions are not safeguarded against losses, all legitimate expenses incident to the construction should be fully included in the cost of the works, if this cost is to be the basis for fixing rates.

In the construction of the Los Angeles Aqueduct it was possible, to an unusual extent, to learn the real cost of the different classes of a great variety of work, as this structure was built on a day-labor basis instead of by contract, and because an accurate system of cost accounting was maintained. The writer was the Assistant Chief Engineer through its entire survey and construction. The engineer who directed and estimated on the work was in a position to follow closely the reasonableness of all expenses through these cost records. The Aqueduct was finished within the estimated cost; the organization was entirely free from politics, and the monies were all expended without scandal on account of waste or graft.

The methods of accounting used on the Harriman System of railroads were used on the Aqueduct; these provide for all work to be authorized by "engineers' work orders". Every item of expense was

Mr. Lippincott.

charged to some specific "work order". Labor distribution sheets and foreman's material diaries were used. The distribution of accounts was made in the field and checked at headquarters, both by a "Cost Engineer" and by the Auditing Department. The total expenditure and the work order charges were balanced monthly.

Mr. O. E. Clemens, an engineer who was engaged in the field during the early portion of the construction work, showed unusual adaptability to the matter of cost-keeping, and, for this reason, he was transferred to the office of the Chief Engineer and given the title of Cost Engineer, in which position he served during the greater portion of the period in which the Aqueduct was under construction. Subsequent to the completion of the Aqueduct, he made the final general summary and analysis of cost data from which the figures given in this discussion were obtained. The system, as developed by Mr. Clemens, was unusually satisfactory and efficient.

The expenditures were divided between the construction of (1) The Waterway and Its Appurtenances; (2) Auxiliary Construction Expenses and Operation; (3) General Miscellaneous Expense and Operation; and (4) General Office and Executive Expense.

"The Waterway and Its Appurtenances" (1) included the finished structure which is left as a result of the effort. This is mainly the conduit which conveys the water.

"The Auxiliary Construction Expense and Operation" (2) included surveys and general engineering of a preliminary nature, water-pipe lines, for construction and domestic use, telephones, roads and trails, buildings, low-tension power lines, division administration (which included superintendents, division engineers, and office force, material handling, sanitation, and housing), miscellaneous tests, expended cement sacks, patrol of the Aqueduct, miscellaneous losses, reorganization expense, concrete replacements, and net equipment expense after its salvage. This auxiliary expense is the largest indirect charge of this nature, and, for that reason, it may be desirable to give some further analysis of this account. It is divided as shown in Table 29.

The "General Miscellaneous Expense and Operation" (3) included passenger transportation for labor, water investigations, sundry adjustments, subsistence losses, unadjusted freights, stock service losses, and miscellaneous operation adjustments. This account was credited with revenues from the sale of domestic water during construction, rentals, and other incidental revenues.

The "General Office and Executive" (4) account included the salaries of all general officers, accounting, disbursing, purchasing department, and legal expenses, executive railroad transportation, and automobile service. Interest charges or development expenses are not included in any of these items.

TABLE 29.—AUXILIARY CONSTRUCTION EXPENSES AND OPERATION (2). Mr. Lippincott.

Items.	Total cost.	Percentage of waterway cost.	Average cost per foot.
Surveys and general engineering	$366 932	2.30	$0.311
Pipe lines, net	281 645	2.77	0.375
" " M. and O.	162 780		
Telephones, net	75 638	0.95	0.127
" M. and O.	75 115		
Roads and trails	274 395	1.93	0.261
" " " M. and O.	34 237		
Building expense, net	336 531	2.10	0.285
Low-tension power lines	59 240	0.35	0.05
Division administration	775 412	4.86	0.657
Miscellaneous tests	39 167	0.25	0.033
Expended sacks	49 553	0.31	0.042
Patrol of Los Angeles Aqueduct	2 672	1.20	0.163
Miscellaneous losses (not including M. O. H. final)	88 130		
Reorganization	28 580		
Concrete replacements	72 752		
Equipment expense, net	1 548 721	9.20	1.31
Totals	$4 271 500	26.72	$3.614

The summary of costs of the aqueduct construction, exclusive of land purchases and cement plants, and the percentages as compared with cost of waterway, were as follows:

(1) Waterway	$15 942 489	.....
(2) Auxiliary expense	4 271 500	26.72%
(3) Miscellaneous expense	277 038	1.75%
(4) General executive	843 944	5.30%
Total	$21 334 971	

Of this amount 33.77% of the waterway cost was for indirect charges. It may appear at first that these indirect charges were unusually high on this Aqueduct because of the remoteness of the work. However, transportation expenses, whether by rail or wagon, were included in the direct cost of the work. The auxiliary charges were practically as great on the end of the Aqueduct next to the City of Los Angeles as they were on the remote portions of the line.

In a large undertaking, these overhead expenses are proportionately less than on a smaller one. This general average was borne out consistently on the different divisions of the Aqueduct. On those divisions where the total construction costs were low, the percentage of overhead was relatively high, and where the total construction costs were high, the overhead charges were proportionately low. On the Los Angeles Aqueduct, during the greater portion of the work, no passenger

Mr. Lippincott.

transportation was paid for labor. As the construction neared completion, however, and the length of time left for finishing the work was becoming short, some passenger transportation for labor had to be paid. The subsistence losses were largely for meals furnished men who never worked any time. These items are included under "Miscellaneous Expense" (3).

The first issue of bonds for the Los Angeles Aqueduct was for $1 500 000, in 1905. This issue bore interest at 4 per cent. This fund was used for the purchase of lands and water rights and for surveys and general investigations. It was followed, in 1907, by an election authorizing the issuance of $23 000 000 in bonds for construction purposes. Of this latter issue, $1 033 600 bore interest at 4% and the remainder at 4½ per cent. The total premium was $77 010, and the bonds were sold as required for funds to carry on the work. The Aqueduct was completed on schedule time in the summer of 1913, and the interest charges on all bonds up to that date (June 1st, 1913) amounted to $3 662 828.43, or 23% of the cost of the waterway. This does not include or take into account the main power-plant construction or interest thereon. This 23% added to the 33.77% for auxiliary expenses actually incurred on the Aqueduct, as previously stated, makes 56.77% total expense for these charges as compared with the actual waterway cost.

On work of a similar character carried on in a less remote region, certain adjustments of these percentages for auxiliary expenses may be made. Roads and trails, buildings and telephones, amounting to 4.98% on the Aqueduct, may be entirely eliminated. The freight on the equipment was a considerable portion of the charges against this item, and the 9.20% may reasonably be reduced to 8 per cent. Other expenses, for replacements, supervision, patrol, etc., should remain the same. We have then for the adjusted Aqueduct auxiliary expenses 26.72% — 6.18% = 20.54 per cent. In the case of work done in a highly developed region, there are more damage claims than on work in a more remote region. The miscellaneous and general executive expenses should not be affected materially. An ordinary work would not involve so long a period of construction, and, consequently, the interest charges would not be so high. However, if consideration be given to the period during which a water-works is being put into full use and earning power, an interest charge of 10% would not be unusual.

Due to the severe employers' liability law that has been passed recently in California, the heavy damages that may be collected by workmen who are injured, irrespective of whether or not they contribute to the accident by their own negligence, introduces an additional new expense in construction work in this State. The ordinary rate for insuring a pay-roll prior to the passing of this new law, against such damage claims, was 1 per cent. The insurance rates at

Mr. Lippincott.

this time amount to $5.25 per $100.00 of the pay-roll for laying water mains, $6.12 for erection of pumping stations, dams, and reservoirs, and $12.25 for tunnel work. Owing to the magnitude of the Aqueduct construction, the Board of Public Works did not carry accident insurance, but settled its own damage claims, charging the losses to "Auxiliary Expense and Operation" account. This loss amounted to 0.26% of the pay-roll. However, this work was performed prior to the time when the new employers' liability law went into effect, and settlements were not made under its provisions. Allowing for the present insurance rates for water-works construction, there should be added to the auxiliary expenses for the above, 5% of the labor cost on the work. These labor costs on the Aqueduct were 60% of all costs, and probably amount to at least one-third of the total construction cost on an ordinary water-works. Consequently, 1.67% should be added for liability insurance in California. From this should be deducted the 0.26% already charged to this expense on the Los Angeles Aqueduct, or, say, 1.40% for a net amount.

All the figures in the estimate of cost of this Aqueduct are based on day labor, without profit. A board of four engineers, of which the writer was a member, was employed by the City to determine the value of the Los Angeles Water-Works which the City was purchasing. In this appraisal it was conceded that allowance should be made for contractor's profit, on the assumption that if a new plant was to be built quickly and without any basic organization, to replace the existing plant, the work would be done by contract and not by day labor, and that a reasonable allowance for contractor's profit would be 6 per cent. The Board states: "After due deliberation it is our firm conviction that a further 6% should be added for a (contractor's) profit." The arbitrators slightly increased these estimates, and the final amount paid was higher. On the cost of the completed structure, 6% would be a low allowance for contractor's profit on the construction of a water-works system.

Therefore, the following estimates of auxiliary cost for work similar to that done on the Los Angeles Aqueduct, adjusted to less remote localities, done by contract, and with 10% allowed for interest during construction, are given:

(2)	Auxiliary expenses	20.54 per cent.
(3)	Miscellaneous expense	1.75 "
(4)	General executive	5.30 "
	Interest during construction	10.00 "
	Liability insurance	1.40 "
	Contractor's profit	6.00 "
	Total auxiliary expense	44.99 per cent.

Mr. Lippincott.

These figures are believed to justify an addition of 45% to the direct construction costs of a water-works of the general class previously referred to, to provide for auxiliary expenses.

In addition, a water-works is usually constructed in a fragmentary or piecemeal manner, and not as one comprehensive undertaking, all of which could be put through in a minimum period of time. Work done in small units is more expensive than if built as a whole, vigorously prosecuted, with ample financial backing, as is ordinarily assumed to be the case in making a valuation report. Cheap work must be done with the maximum organization that can be placed on the entire job efficiently, in order to reduce overhead expense. This argument would justify using higher unit cost figures, in making a valuation, than those which are available from a large piece of work that is built under full headway.

The writer believes that we have reached the time when the investors in many of the securities of public utilities need helpful support in the matter of reasonable rate fixing. Irrespective of indiscretions and bad management in the past, we should look forward to reasonable service and fair treatment in the future. If these institutions are not to be guaranteed against loss, and are only to be permitted to earn such reasonable interest on their investment as could be obtained from first-class mortgages or established commercial enterprises, then certainly, in determining the value of the property, due weight should be placed on all legitimate expenditures, including auxiliary costs. If this is not done, it will follow that either the service will deteriorate or the investors will refuse to continue to place funds in institutions of this nature. In the Southwest there is a decided movement on the part of utility corporations to dispose of their properties, even at a sacrifice, in order to terminate the contentious strife with the public. The California Railroad Commission expresses a realization of this situation in its findings in the Palo Alto Gas case:

"This brings me to a consideration of the final question in the case, namely, the amount of return to be allowed the Gas Company on its plant. No fixed percentage applicable to all cases and all classes of utilities can be established by this Commission. Each case must be judged on its own merit. It may be well that a utility in one community would be entitled to one rate of return while a similar concern in another community would be entitled to a different rate. It may be that a large and solidly established utility will not be entitled to as high a return as a smaller utility which is struggling against adverse circumstances. The most that can be said by way of general principles is that the return should be at least the average return which is earned by other classes of business of the same degree of hazard in the same community. The Commission in fixing a rate of return must be liberal, lest too strict a policy result in turning capital to other fields of enterprise. California needs development by public utilities, and this

Mr. Lippincott.

Commission's policy should be a broad and liberal one, so as to encourage capital to develop the State by legitimate public utility enterprises where needed. The Commission should be careful not to permit an inflation of prices in ascertaining the value of the property of a public utility used and useful for the public purpose, but should be liberal in establishing the rate of return on that value. Bearing in mind all the facts of this case as shown by evidence, I find that a rate of return of 8 per cent. on the value of the property of the Palo Alto Gas Company used and useful for the puplic purpose, as fixed herein, is at least a fair and equitable rate of return. If anything, the rate is too high by reason of the fact that the Commission has been more than liberal in establishing the basis of value."*

In certain rate-fixing litigation before the California State Railroad Commission at the City of San Diego, in which that city was made a defendant in the complaint that originated from certain consumers outside of the city who were served from the municipal system, the Engineering Department of the Railroad Commission in its estimates of the value of the property, made the following allowances for overhead or auxiliary charges for the construction of the Otay and Moreno Dams and the Delzura Aqueduct, the total construction amounting to $2 900 000:

Engineering	5	per cent.
Contingencies	7	"
Interest for 3 years	9	"
Legal and general expense	2	"
Liability insurance	3	"
Total	26	per cent.

The writer is informed that these are the highest overhead charges that have been allowed for work of this character by the Engineering Department of the California Railroad Commission. It is fully realized that exception may be taken by some to the classification of the accounts on the Los Angeles Aqueduct, and the relatively high auxiliary expenses shown by this method of classification, but it is believed that the items are given in such detail that others may reclassify them in such a manner as to compare them with their own expenditures and with other distributions that have been made on other work.

Mr. Noble.

ALFRED NOBLE, PAST-PRESIDENT, AM. SOC. C. E.† (by letter).—The writer believes that the subject of valuation is of such great importance that discussion should be continued at future meetings of the Society.

* Opinions and Orders of the Railroad Commission of California, City of Palo Alto *vs.* Palo Alto Gas Co., Vol. 2, pp. 316-317; Opinion of Thelen, Commissioner.

† This discussion was forwarded by Mr. Noble a short time before his death, and, consequently, could not be revised by him.

Mr. Noble. As one of the Committee responsible for this report, he desires to state that it represents the unanimous view of the six members of the Committee participating in its work, after two years of study. It does not follow that its conclusions are correct, and it is hoped that full discussion will disclose errors, if they exist.

The most general objection to the report is in regard to the treatment of depreciation. The Committee's plan provides for income through rates to return to the investor his capital in installments, corresponding with the estimated reduction of value through depreciation. If the investor receives, through rates, a return of the full investment, together with reimbursement of operating, maintenance, and other necessary expenses, and a due allowance for use of capital, risks, and management, it is claimed that he is justly treated and has no further claim on the public. If, instead of diverting to other uses the installments received on account of investment, he reinvests in extensions or replacements, on which fair earnings are allowed, he is receiving fair treatment from the public. If the Committee's plan does not accomplish this, it is faulty. It seems to the writer that the criticisms are in greater part due to misunderstanding of the Committee's recommendations. The Committee regards it as improbable that a large sinking fund will be maintained under any circumstances, because the owner of the property can make the money earn more by other investments; the preferable investment, where practicable, would be for extensions of the plant, if the money were not needed at the time for replacements.

The Equal-Annual-Payment Method has been proposed in order to make the collections from the public as nearly uniform as practicable during the life of the property, the increasing payments on account of return of investment balancing, or nearly balancing, the decreasing payments for use of capital. This is entirely consistent with the idea of a uniform rate for the same service, whether the items of the plant are new or old.

The return to the investor by the Equal-Annual-Payment Method differs from the Sinking-Fund Method, as usually understood, in this, that the sum of the annual returns of capital equals the investment without the inclusion of interest.

The writer's object in presenting this brief discussion is to ask careful examination of the Committee's plan, and to express not only confidence that it is based on justice to all, but a willingness to modify or abandon it, if it can be shown that this confidence is unwarranted.

Mr. Byers. M. L. Byers, M. Am. Soc. C. E.—After considering what has been said on this subject, it seems to the speaker that perhaps the time is opportune to endeavor to emphasize one or two points, and perhaps to ask the Committee for a little further explanation of the practical

application of its theories of valuation for rate-making, having in mind that it is stated (page 6), that "the valuation is for the purpose of determining rates which shall be a limitation of charges to those which will give a fair return and no more." Mr. Byers.

I.—The Courts state, and it seems equitable to assume, that, in the regulation of rates, the property is entitled to a fair return on its fair value.

$$\text{Fair Return} = \text{Fair Value} \times \text{Fair Rate of Return}$$
$$= \text{Output} \times \text{Tariff Rate (or Unit Selling Price)} - \text{Cost}$$

or,

$$\text{Tariff Rate} = \frac{\text{Fair Value} \times \text{Fair Rate of Return} + \text{Cost}}{\text{Output}} \quad \ldots\ldots\ldots (A)$$

As the tariff rate is something that is to apply to future earnings, apparently we must deal with fair value, and fair rate of return of the immediate future, as a practical proposition—what it would probably be for a year, or whatever period would elapse before the next time of revaluation, or readjustment of rates.

In Equation *A* fair value is determined through the process of valuation of the property. It being "the reasonable value of the property at the time it is being used for the public" which must be used, this varies with changes in the prices of labor and materials, land values, additions and betterments carried out, etc., etc.

Fair rate of return is a quantity which varies with the risk of the enterprise and with the value of money. The value of money is constantly fluctuating, and, therefore, for practical purposes, this must be based on the estimated average risk of the industry and the estimated average value of money during a reasonable period of the future. It cannot be determined accurately, but must be estimated by application of experience and judgment to the problem.

Cost is an item which must be estimated. It depends on output, and output will be greater or less in the railroad business, depending on the tariff rate. If the tariff rate is placed so high that it prevents the business from being handled, the output will be reduced, and the unit cost will naturally be increased because of the overhead charge. Cost also includes a number of items, such as, maintenance, cost of operation, etc., including depreciation.

Output is an item which, in the railroad business, depends on the condition of prosperity of the country, the state of the crops, the tariff rate which is adopted in a particular case, etc. If we have rainfall at the proper time, then the output will be increased. Aided by experience, these must be forecasted in determining and estimating output, which is to be applied in the determination of the tariff rates to be used in the future.

Mr. Byers.

It is clear that, in applying this equation to a gas plant or other utility of that sort selling one commodity, it is comparatively easy to solve, even though the various factors seem to be not of the most definite. When it comes to applying it to a railroad, the speaker must confess that he would like the Committee to go into a little detail as to the practical application of its theories, for now Equation (*A*) becomes:

$$\underset{\text{(thousands of them)}}{\text{Tariff Rates}} = \frac{\text{Fair Value} \times \text{Fair Rate of Return} + \text{Cost}}{\underset{\text{(thousands of them)}}{\text{Outputs}}} \ldots (B)$$

There is still only one equation, but there now become thousands of unknown quantities.

Consider a system like the Pennsylvania Railroad, or the New York Central, or the Southern Railway, or any of the large railway systems. There are hundreds and thousands of stations, there are dozens of terminals, each one of which means a different amount of plant applied for the purpose of transportation.

It is common knowledge that, in the passenger business, passengers are carried over quite a number of lines, and are carried various distances. Under present practices, one passenger is charged one rate to-day because he buys a single-trip ticket; another passenger pays a little different rate because he buys a return ticket; still another passenger going between the same points is charged a little different rate because he buys a fifty-trip ticket; still another passenger has a mileage book, and he pays a different rate. Now, one important thing to emphasize in this particular is this: that these passengers have built their homes, many of them at different places, on different lines, because they could travel at those particular rates. They have their investments made.

The freight situation is the same throughout the whole country. Plants all over the United States have been located where they are, because, under the rate system now in existence, those were the economical places to locate those particular plants. Those rates have not been determined on any such basis as this. They have been determined through the influence of many factors.

If it is attempted to substitute for this system of rates which has been developing in this country for 50 years, a new system built on an entirely different basis, what will be the results to the industries which have been economically located on the entirely different present basis? This point is raised simply to emphasize the importance of this question and the danger of throwing the weight of this Society's influence for or against this proposition without due consideration.

It not only affects the railroads' interests, but millions and millions of capital invested in every form of industry.

Mr. Byers.

The bituminous coal traffic furnishes an interesting point of view from which to consider the use of "Valuation for the Purpose of Rate-Making." An enormous quantity of bituminous coal is carried by various railroads to the Great Lakes for transportation across these lakes to points of consumption beyond. Many coal fields, such as the Brazil, the Ohio No. 2, the Ironton, the Pocahontas, the Kanawha, the Fairmont, the Pittsburgh, the Connellsville, etc., supply the coal for this traffic. These coals compete with each other in the Great Lakes markets, commanding prices at such common terminal points, which depend on the relative qualities of the coals and on no other factors. For example: Pittsburgh coal, due to its better quality as a gas coal, commands a price about 10 cents per ton higher than Ohio No. 2 coal. The cost of mining these different coals per ton varies greatly, depending on the thickness of the seam, character of the roof, equipment of the mine, daily output of the mine, wages of the miners, etc. The distance of the coal from the common markets varies by hundreds of miles by air line, and by railroad routes over which it is transported. The cost of transportation to the railroad company varies with the distance, grades, etc. Under the competitive conditions of to-day and of the past the wages of the miners in the different fields, the freight rate per ton (not per ton-mile), and the selling price of the coal at the mines, have been worked out so that the net profits of the industry (market price minus actual cost of mining, transportation, etc.) are divided between the different parties at interest, namely, the miner, the mine owner, the railroad, etc., on the basis which such free competitive condition has established to be equitable.

May it now be asked of the Committee how, in its opinion, it is possible, bearing in mind such complication of service rendered by the railroad, to utilize "Valuation for the Purpose of Rate-Making" and if, in its opinion, under the peculiar methods and conditions which it would seem must be used (if it can be done at all) in the application of valuation to this purpose, it has included in its report all the factors which must enter into a valuation to be used under such unusual circumstances? To one who has had experience in railway operation, but who has not had experience in the facility with which valuation is applied (no doubt) to the simpler provinces of rate-making for gas and similar utilities, it would be a material source of satisfaction if the Committee could feel it to be a part of its duty in the making of a report on "Valuation for the Purpose of Rate-Making" for a railroad, to indicate how such valuation is to be practically applied.

Assume, for example, that valuation is to be applied for the purpose of rate-making to the railroad which hauls Ohio No. 2 coal (as well as other products) to the Lakes, there to meet the competition

Mr. Byers.

from the other coalfields transporting their products over other railroads. In order to determine tariff rate, it is necessary, among other things, to estimate both cost of operation and output; but the tariff rate on the Ohio No. 2 coal, which is arrived at as the result of the application of this valuation data, may be so high as to prevent entirely the movement of this coal; or the rates established through valuation on other lines may prevent the movement of the other coals and give the entire market to the Ohio No. 2 coal. There is nothing said, in the Committee's list of principles, about the necessity for first valuing and establishing rates on all competing lines before attempting to value and establish rates on the line which is the immediate subject of the inquiry. Yet, how else could the Committee be enabled to compute either cost or output for the line transporting Ohio No. 2 coal, and, in the absence of these figures, how could the valuation be used "for the purpose of determining rates which shall be a limitation of charges to those which will give a fair return and no more?"

It would seem that the Committee was well within the bounds of fact when it stated (page 67): "There are several reasons why a physical valuation, taken by itself, furnishes an unsatisfactory basis for determining rates."

II.—In three ways, the Committee has made the discussion of its report unusually difficult.

In the first place, though the application of its recommendations to railroad properties is, at the present time, probably of the maximum interest, practically all its illustrations and applications of principles are to other public service corporations, differing very much in character from railways.

In the second place, although the Committee is dealing with a subject about which there is a very great amount of misapprehension and looseness of use of terms, it does not furnish definitions of the terms which it uses, and these terms, as applied to railway properties, become, many of them, extremely uncertain in their meaning.

Lastly, it frequently states its view without explanation or proof of its correctness, as where it states, as one of the general principles involved in valuation for rate-making (page 6): "It has been well settled by the highest Courts that the owner of such property is entitled to a fair return upon the fair value of the property utilized in or reasonably necessary to the service," and omits the important additional provision that it shall be a "fair return upon the reasonable value of the property at the time it is being used for the public." Another example: On page 67, the statement is made, "Embankments and the slopes of cuts may become more stable on account of the growth of grass and weeds, and may therefore be considered to be more valuable, but such value as this, which is not the result of

expenditure by the corporation, should have no place in the valuation of the property." Why not, as it represents value at the time of public use? Mr. Byers.

On page 69, it is stated:

"It has been held by the Committee that the unfavorably located public service property is not entitled to more than reasonable rates for the service it renders even though the property in question becomes a losing venture; conversely, the Committee believes that the favorably located older property should equitably receive liberal treatment by rate-making bodies."

Applied to railroad property, what does the Committee mean by "unfavorably located public service property" and by "unreasonable rates"? The New York Central and Hudson River Railroad follows the east bank of the Hudson River from Albany through Poughkeepsie to New York, whereas the West Shore Railroad follows the west bank from Albany through Newburgh to Hoboken, and *via* ferry to New York. Presumably, the Committee has in mind that, with reference to the Albany-New York business, the West Shore is an unfavorably located public service property as compared with the New York Central. Does it, however, consider the West Shore to be comparatively unfavorably located with reference to business handled between Albany and Newburgh, or between Newburgh and Hoboken, and would it call the New York Central an "unfavorably located public service property" because it cannot transport between these points as conveniently or economically as the West Shore? Probably without exception, every railroad serves some territories that are not served by any other railroad. How then, can any railroad be said to be an unfavorably located public service property, and if there is no such thing as an unfavorably located public service railroad property, then wherein does the quoted view of the Committee apply?

Old timers relate that, years ago, prior to the construction of certain narow-gauge railroads in the oil fields of Northwestern Pennsylvania, it was necessary to haul boilers and other apparatus for well-drilling plants many miles by teams of horses. When the railroads began to reach these developing territories, they adopted a freight rate for the transportation of boilers just a few dollars below the cost of transporting them by teams. Evidently, even this reduction in cost was a benefit to the shipper. Does the Committee consider such a rate as unreasonable under the circumstances, recalling that the traffic was light and high rates were necessary in order to pay a fair return on the cost of the railroad property? If the Committee does not regard this as an unreasonable basis of rates under the circumstances, does it not follow that, where necessary to earn a fair return on the fair value of a railroad property, any rate which

Mr. Byers.

is low enough to permit the business to be moved by rail as against movement by other forms of transportation is a reasonable rate?

III.—The fundamental law governing the use of capital is that it will flow to the point where, risk considered, the prospect of remuneration for its use is the most enticing, and that it will flow away from any point where the prospect of remuneration, risk considered, is not satisfactory as compared with investment opportunities elsewhere.

Capital invested in fixed property, by reason of its immobility, is more vulnerable to injury than liquid capital. The latter, it has been found, after all sorts of efforts to control it, is absolutely free and can only be enticed, not commanded.

In estimating the risk of an investment in fixed property, capital is guided largely by previous experiences with such investments. If previous experience shows that it has been enticed into such investments by false pretenses and has afterward been robbed of the advantages promised it, the result will naturally be an appreciation of the item of risk and a consequent increase in the rate of remuneration demanded for this type of investment in the future.

If, for example, capital is enticed into the transportation industry by the promise of land grants, bonuses, etc., and, later, finds that efforts are made, whenever opportunity offers, to strip it of the fruits of such grants, gifts, etc., through direction or indirection, the result will be to make capital more wary of and to demand higher returns from investments in such industry in the future.

Always, when capital considers investment in any enterprise, it has two fundamental considerations before it:

A.—What of the conditions of return of this capital proposed to be invested?

B.—What of the remuneration for use during the period of investment?

Return of capital is made in two principal ways:

1.—Direct return, as when a mortgage matures and is paid off.

2.—Indirect return, as when the property is sold. In this class, the chance of appreciation or depreciation in sales value must be reckoned with.

The rate demanded by capital for its use is determined by two principal factors: the current value of money (depending on ratio of supply and demand) and the insurance rate demanded by the intensity of the risk.

It is not greatly material, a common understanding being assumed, how this total rate is made up, the principal point being the size of the total. For example: If it requires a return of 8% to entice capital into the transportation industry, it is immaterial to capital whether the

total amount represented by this 8% return is the result of a straight 8% return on the total amount of the capital invested; or a 10% return on 80% of such capital (the computer amusing himself with the idea that the 20% of capital eliminated is something which he terms depreciation); or a 6% rate on the original capital investment, plus an allowance equal to 2% on such capital, such allowance representing an 8% return on what the computer is pleased to term appreciation. The important point to realize is that, barring deception, unless the computer handles his computations so that the necessary total is reached, capital cannot be attracted into the enterprise. Mr. Byers.

On page 50, of the report, the Committee states:

"The present practice generally gives to the corporation, as to the individual, the so-called unearned increment due to appreciation in land values.

"This is incompatible with the fundamental principle that the corporation is entitled to fair return upon the fair value of its property, because, if the land is valued at the increased price, and the appreciation in value of the land is not included in the accounting, the corporation would receive a sum in addition to a fair return amounting to the appreciation in the value of the land."

On page 52, the Committee states in part:

"Where the valuation cannot be made in this way [that is, by taking the cost of recently purchased land], it is the view of the Committee that land can be valued most correctly on the basis of present price of neighboring land of similar character, augmented by the ratio ordinarily found to obtain in that region between land acquired by public service corporations on one hand, and by private parties on the other."

These two principles appear to conflict; for in the second quotation it is clearly intended that there shall be included in fair value the present value of the land, regardless of the fact that this present value is the result of past appreciation. Presumably, the Committee intends that the statement first quoted shall apply only to further appreciation of land after the date of the valuation. Does not the truth of this proposition, however, depend on the definition which the Committee intends to adopt for "fair rate of return", bearing in mind that it is not the method of computation of the fair rate of return, but the amount of such rate, which is essential in attracting or repelling capital? Most industries include land among the properties owned and used therein, and it seems reasonable to assume that the owners in each case expect to secure, in some form, whatever value accrues from the appreciation thereof. When it is said that a certain corporation earned 12% on its capitalization, this is, in the usual sense of the term, in addition to whatever appreciation in values may have occurred during such period. Is not the Committee injecting a very unusual meaning into its use of terms, and one

Mr. Byers.

better calculated to confuse than to clarify the discussion? Certainly if, in other industries of equal risk, it is possible to earn a certain percentage on actual investment, augmented from time to time by land and other appreciation, then fair promise of similar earning must be extended to induce capital to enter the railroad industry.

It is often to advantage to use an extreme case for the purpose of illustration. Let it be assumed, therefore, that a certain corporation begins business with a capital of $1 000 000, of which practically nothing has been expended for land, although a considerable tract of land has been acquired and is used in the industry. The corporation earns, at the start, 10% on its capitalization of $1 000 000. Twenty years later everything with reference to the business and capital of the corporation is unchanged, except that the actual sales value of its land now amounts to $1 000 000. If the corporation went out of business, a new corporation would be obliged to invest $2 000 000 of capital in order to continue the business, and it certainly would expect to earn a fair rate of return—say, 10%—on such $2 000 000 capitalization. Is it not unjust, therefore, to require the old corporation to earn but 10% on the original outlay instead of on the present value? Moreover, how does the Committee reconcile its position in this matter with the statement of the Federal Supreme Court in San Diego Land and Town Company *v.* National City, also quoted with approval in the Minnesota Rate Case Decision, which reads as follows:

"What the company is entitled to demand in order that it may have just compensation is a fair return upon the reasonable value of the property at the time it is being used for the public."

Perhaps the Committee intended to convey the meaning that failure to allow unearned increment was intended simply as a practical measure existing only during short intervals and for the purpose of reducing clerical and similar difficulties. This would seem to be borne out by its statement on page 50, as follows:

"Your Committee therefore recommends * * * that the land or other property which appreciates in value be valued at present prices, and that the appreciation in the value of such property be offset against the depreciation in the value of the other property."

If such is the case, it is suggested that the situation be cleared up and that a number of definitions would be of material value in this connection.

IV.—On page 65, the Committee states:

"From the time that a public service commission is authorized to control rates, to fix the amount that the corporation may earn as a depreciation allowance, and to control methods of accounting, it is desirable and proper to take into account the excess or deficiency of earnings."

Mr. Byers.

Does the Committee really consider that, the commission having authority to control rates, the fixing of the depreciation allowance and the control of the methods of accounting are items of consequence having bearing on the propriety of taking into account the excess or deficiency of earnings? Is not the control of rates the one essential factor? Is the Committee to be understood as stating that, in its opinion, in any valuation of the railways of the United States, "it is desirable and proper to take into account the excess or deficiency of earnings" since the appointment of the Interstate Commerce Commission with authority to control rates, and that prior to this date the insufficiency or excess of earnings of railways have "nothing to do with the case", as indicated by its statement (page 65): "It is the view of the Committee that an excess or deficiency of past earnings of an unregulated property should not be considered in making a valuation of the property," or does it take the view expressed (page 9) that, "in the case of a property recently created, with accounts kept properly, the best basis for a valuation is the actual reasonable cost as shown by the accounts," assuming that such a property could be found.

Mr. Stearns.

FREDERIC P. STEARNS, PAST-PRESIDENT, AM. SOC. C. E.—The Committee will not be able to close the discussion of its Progress Report on Valuation for the Purpose of Rate-Making before the latter part of the year, and the speaker thinks it desirable to reply sooner to certain features of the discussions printed in the February and March *Proceedings*, and of the oral discussions at the meetings of March 11th and April 2d, 1914.

One of the most common criticisms of the report of the Committee is that it should not have reported on valuation for the purpose of rate-making.

The Committee has stated in its report that valuations for different purposes necessarily differ in some respects, and it took up first the one branch of the subject indicated by the title of the report. It is rather surprising that there is criticism of this proceeding expressed in so nearly the same terms by so many of those discussing the subject, because the matter has been previously discussed by the Society without such criticism.

For instance, in 1912, C. E. Grunsky, M. Am. Soc. C. E., presented a paper entitled "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates".* In 1913, William J. Wilgus, M. Am. Soc. C. E., presented a valuable paper on the "Physical Valuation of Railroads",† which begins as follows:

"The Herculean task of valuing the railroads of the United States is of vital importance to the entire nation, whether viewed from

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 770.

† *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 203.

Mr. Stearns.

the standpoint of rate regulation or its possible outcome, government ownership."

At several places in this paper and in the discussions which followed, reference is made to valuation for the purpose of rate regulation, and to the difference between valuation for purchase and sale and valuation for rate regulation, it being claimed that value new should be used in connection with rate regulation.

Onward Bates, Past-President, Am. Soc. C. E., in the opening statement of his discussion* of the Committee's report, says:

"The valuation of public utilities for the purpose of rate-making is one of the great economic questions of the present day in the United States."

In the speaker's opinion, the physical valuation is the most important factor entering into the valuation of public utilities for the purpose of rate-making, and this Society includes the men who are best capable of making a physical valuation of such properties.

Mr. Robert H. Whitten, in his comprehensive work, "Valuation of Public Service Corporations", states:

"Official valuations of the property of public service corporations are made for four general purposes: (1) Taxation; (2) Accounting and capitalization; (3) Public purchase; (4) Rate-making."

And his treatise is devoted mainly to valuation for rate-making and public purchase.

The United States Supreme Court has consistently ruled for many years that public utilities are entitled to a fair return on the fair value of their property, and a very important element in the value of a property is its physical value.

A Federal Judge in California, who has had much to do with very important rate cases, stated that the most important fact to be determined is the value of the property.

Many of those who criticize the Committee for making a report on valuation for rate-making remind one of the defendant in the case of the borrowed kettle—first, that it was not borrowed; second, that it was cracked—and suggest that though valuation for the purpose of rate-making may be applicable to other utilities, it is not applicable to railways.

C. W. Hudson, M. Am. Soc. C. E.,† one of the critics of this feature of the Committee's report, goes so far as to hold that a railway is not a public utility, as he says it "appears advisable to the writer to separate the rules and methods for valuing public utility properties from those for valuing railway properties."

---

* *Proceedings*, Am. Soc. C. E., for February, 1914, p. 341.

† *Proceedings*, Am. Soc. C. E., for March, 1914, p. 713.

Mr. Stearns.

These criticisms lead the speaker to ask, wherein is there a fundamental difference between the property of railroads and other public utilities, which affects the general principles to be applied in valuation for rate-making? Is not the railroad, as well as any other utility, entitled to a fair return on the fair value of its property? Is it not entitled to an annual allowance for depreciation to cover the lessening value of the various items of perishable property? If its value is to be determined, is it not entitled to have included the overhead charges and development expenses, as much as any other public utility, and is it not proper for this Society to discuss how all these subjects shall be treated to produce the most equitable results?

There are many features, not taken up in the report, which need consideration, such as the effect of competition and of interstate conditions, and as Commissioner Maltbie stated, when discussing this subject, "there is no one yard-stick which will apply to all cases."

Every case is likely to present different conditions, and a public service commission charged with the duty of rate regulation will necessarily be confronted with special problems in different cases, which are likely to modify its action. The fundamental principles are the same in all cases.

If railroads are to be excluded because they are competitive and interstate, why should not all other competitive and interstate properties also be excluded, such as telegraphs, telephones, interurban street railways, pipe lines, expresses, etc.?

The speaker is pleased to note that the fundamental principles which the Committee has presented have not been seriously attacked in any direct manner, although they are ignored in much of the discussion. One of these principles is that the owner of the public utility is entitled to a fair return on the fair value of the property utilized in or reasonably necessary to the service. Another is that in any regulation of rates "there shall be taken into account two distinct features:

"First, the annual return, covering interest and profit, to which the corporation is entitled for the use of its capital, having in view the risks incidental to the investment.

"Second, an allowance sufficient to provide for the net depreciation in the value of all the items of physical property, whether resulting from decay, wear and tear, or other cause, the amount of such depreciation allowance to be sufficient to amortize all such items of property by the time they cease to have value."

Many have attacked indirectly the second of these general principles, holding that it is enough to earn and lay aside only the sums required for the renewal of plant units when they reach the end of their life. Such allowance as they would provide for depreciation, which they

Mr. Stearns.

sometimes term "deferred renewals", is much less than the annual sum which the Committee believes the corporations are entitled to earn on account of depreciation.

In addition to the fundamental principle that the corporations are entitled to annual returns for the use of and waste of capital, it is obvious that they are entitled to be reimbursed for current expenses, including taxes, and that there are other factors entering into the determination of rates.

The Committee also regards it as fundamental that the rates should be made large enough to be attractive to capital, and expressed the view that "the public may be as injuriously affected by too low as by too high rates".

Several members have criticized the Committee on the ground that it has shown deference to the opinions of the Courts, and one member thought it did not show deference enough. There is no doubt that a Court is fallible, and that, in many matters, it is dependent on the testimony and arguments brought before it, but when an able Court, like the Supreme Court of the United States, composed of men who are able to take a broad view of matters which are presented to them, makes a decision to which it adheres consistently for many years, such decision should be deferred to, for two reasons: First, that it is probably a just decision; second, that it represents the highest law of the country, and a neglect to comply with it in cases coming before the Courts will result in failure.

The decision of the Supreme Court which is especially objected to is that relating to depreciation in the case of Knoxville *vs.* Knoxville Water Company, which, in the judgment of the speaker, is logical and just, and, within the speaker's knowledge, has produced higher returns for a corporation than it had been permitted by a rate-making body to receive prior to that decision.

The decision referred to was given in a rate case, and states clearly that "some substantial allowance for depreciation ought to have been made in this case" from the cost of reproduction. Four years later, in a railroad case, the same Court affirmed the same view by this statement: "and when an estimate of value is made on the basis of reproduction new, the extent of the existing depreciation should be shown and deducted". The decision also says: "It is also to be noted that the depreciation in question is not that which has been overcome by repairs and replacements, but is the actual, existing depreciation in the plant as compared with a new one".

It is better to defer to such well-established rulings of the Court, and to adopt methods of depreciation which will give equitable results under such rulings, than to adopt other methods which will be confiscatory if the Courts continue to rule in accordance with this well-established precedent.

Mr. Stearns.

It seems to the speaker that those so strenuously claiming value new and the smaller annual sum for depreciation which properly goes with it, while the Court decisions are as they are, occupy much the position of a man who wishes to walk to a destination beyond a high stone wall. There are two paths of equal length leading toward this destination: On one the opening has been closed, and on the other the opening is still available. The man would be successful in reaching his destination who goes by the unobstructed path.

C. B. Burdick, M. Am. Soc. C. E.,* apparently thinks that the Committee has not deferred sufficiently to the decisions of the Courts, and asks: "Has the Committee had the opportunity to consider the matter sufficiently to warrant it in recommending procedure at variance with the law as established by the higher Courts?". He adds: "The law is the outgrowth of the experience of centuries".

There are many matters connected with valuation on which the Courts have necessarily acted, but which cannot yet be regarded as well settled. Unprejudiced and intelligent discussion should aid in settling them correctly.

Several have discussed the question as to whether present or original physical conditions should be adopted in making an estimate of the cost of reproduction of an old property. It is recognized that changes are continually occurring, which greatly affect the cost of reproduction of a property, as, for instance, a pavement may be placed over a water pipe which was laid before there was a pavement; or a railroad may be built so as to give access to a dam which was originally built at a long distance from the railroad.

Owing to such changes as these, if present conditions are to be used, the cost of reproducing the water pipe would be largely increased by the cost of taking up and replacing the pavement, and the cost of the dam would be greatly decreased by reason of the diminished cost of providing all supplies and materials under the new conditions.

The Committee has taken the view that the unearned increment, or the unearned decrement, resulting from these changes is not required by any consideration of equity, and that when the estimated cost of reproduction is based on original physical conditions the most equitable results are obtained.

Of those who have discussed the subject, J. E. Gibson, M. Am. Soc. C. E.,† argues that the owner of a public utility is entitled to the unearned increment of value due to highway improvements constructed by the public, but he intimates that a decrement resulting from applying present conditions should not be treated in the same way, as he says:

* *Proceedings*, Am. Soc. C. E., for March, 1914, p. 706.

† *Proceedings*, Am. Soc. C. E., for February, 1914, p. 368.

Mr. Stearns.

"The board of appraisers, in considering the present conditions of the plant, should also consider the conditions existing previous to the commencement of construction; otherwise, the utility might be done a great injustice."

Henry Floy, M. Am. Soc. C. E.,* believes in reproduction new under present conditions.

Allen Hazen, M. Am. Soc. C. E.,† apparently takes the same position as Mr. Floy, as he does not admit that the history of a water pipe "has anything to do with the cost of reproduction of the property as it now stands, or with its value".

Mr. Burdick shows the Committee's position in the matter of present or original conditions quite well when he says:

"It would seem that the Committee has shown a leaning toward investment as a measure of value for the purposes of rate-making, but through the influence of Court decisions, which are numerous and strong, had been forced to the adoption of present prices in the estimates of value".

The use of present prices prevailing at or near the time of valuation is made necessary by Court decisions, and also may be defended on the ground that it is the usual custom in valuing properties. The owner of the utility in this instance does not get an unearned increment or decrement, because he has to take the risk of both increase and decrease in prices. It is not desirable, however, that there should be changes in the valuation of property owing to changes in prices, and this can be avoided in the future with suitable legislation and with continuous commission control, as has been pointed out by the Committee.

In reference to the criticism that the Committee should be consistent and either use original prices with original physical conditions or present prices with present physical conditions, the speaker sees no inconsistency in the Committee's recommendation. The increments and decrements of value due to rise and fall in prices appear to be unavoidable under present conditions, but this does not furnish a reason for introducing increments and decrements due to changing physical conditions, especially as, in many cases, they would be very large.

Mr. Burdick says: "It would seem most logical in the valuation of these properties to pursue one logical method through to the end. If it be the cost of duplication at present, then reproduce under present circumstances", and yet, referring to the reproduction cost of a reservoir, he does not accept the present circumstances under which the railroad passes around the reservoir, but reverts to original conditions and says: "If a railroad formerly occupied the site of the reservoir,

* *Proceedings*, Am. Soc. C. E., for April, 1914, p. 1126.

† *Proceedings*, Am. Soc. C. E., for March, 1914, p. 713.

it would be entirely reasonable to assume that it would necessarily be removed in reproducing at the present time". Mr. Stearns.

The next point to be taken up is the question as to whether value new should be used in all cases where a valuation is made for the purpose of rate-making.

A very large number of those discussing the Committee's report contend that value new should be used in all cases. They do not discriminate, as the Committee has done, and state that value new should be used with some methods of providing for depreciation and not with others, but apparently claim that it should be used in all cases.

George F. Swain, Past-President, Am. Soc. C. E., has presented this view in the most extended and forceful manner, and his discussion will be the basis of the speaker's remarks on the subject. It may seem rather ungracious to select his discussion for criticism in this respect, because he has paid the Committee the high compliment of commenting favorably on all parts of its report except that relating to depreciation, and signifies his agreement with its conclusions as to most of the other features of the report.

In regard to the subject of depreciation, he believes "that the views of the Committee are lacking in clearness, that they involve confusion of thought and are misleading". A comparison of the views of the Committee and of Mr. Swain is, therefore, in order.

First, as to fundamental principles. the Committee, in its report (page 32), takes the view that:

"The corporation, under normal conditions, in addition to an annual return for the use of its capital, is entitled, as already stated, to an allowance sufficient to provide for the net depreciation in the value of all the items of physical property, whether resulting from decay, wear and tear, or other cause, the amount of such depreciation allowance to be sufficient to amortize all such items of property by the time they cease to have value."

It also takes the view that the money received by the corporation for depreciation allowances should not be returned to the stockholders as a part of the income of the property, but should be retained as a part of the capital account. In portions of his discussion, Mr. Swain appears to be in entire accord with these views of the Committee. He says:

"The Committee is perfectly right in stating (Addendum, page 3): 'that the owner of a public utility property is entitled to have the rates made high enough, under normal conditions, to pay for the lessening value of the perishable property, so that when such property goes out of use he shall have received, not only a fair return for the use of the capital invested in such property, but shall also have the capital invested in it paid back to him,' except that the original capital should not be paid back to the investor, but should be held by the corporation for renewal when the time comes."

Mr. Stearns.

His exception does not represent a radical difference from the views of the Committee, as it fully agrees with his statement "that the original capital should not be paid back to the investor", and differs in regard to the last part of the exception only in the fact that the Committee would have the capital paid back to the owner of the property reinvested in the property when practicable, without regard to whether the reinvestment is in additions or renewals, and when this course is not practicable held temporarily in a reserve fund or used for retiring outstanding obligations.

In another place he makes this statement, regarding the fundamental principles of depreciation:

"In the speaker's opinion, the method of depreciation to be allowed is an accounting problem, the object being simply to set aside out of earnings each year such sum as may enable all renewals in kind to be made without any increase of capital."

After the endorsement of the statement made by the Committee, this is somewhat "confusing", as it limits the earnings on account of depreciation to the sum which will enable all renewals to be made without increase of capital, but makes no provision for obsolescence.

He refers to the depreciation allowance as being "a payment to the corporation and not to the stockholder who has invested his money", and adds: "It is a payment which should not reach the stockholder, but should be held by the corporation for a specific purpose." This is in entire accord with the views of the Committee.

After this declaration, it is somewhat "confusing" to find the statement that it is not of any consequence to the rate-payers, as such, "what the company does with the depreciation allowances which they have paid. It makes no difference to them whether the company puts these depreciation allowances in a fund * * * or whether it distributes them as dividends"; and then a later statement: "The rate-payer, of course, is concerned that the depreciation funds should be safely invested."

Many rate-payers have found to their sorrow that depreciation funds distributed to the stockholders as dividends are not "safely invested", and that the practice has resulted in unsatisfactory service and in demands for higher rates.

Mr. Swain claims that value new should be used with the Straight-Line or Equal-Annual-Payment Methods of depreciation, as well as with the Sinking-Fund Method.

The speaker will test this view by an example, using the item of property referred to in the Committee's tables on pages 34 and 40 of its report. The assumption is a property having a 20-year life, valued when new at $100, and with computations of depreciation allowances based on 5% interest compounded annually. If such a property is to

be valued new under different methods of depreciation, the annual allowance for depreciation by the Sinking-Fund Method would be $3.02, and by the Straight-Line Method, $5.00. Mr. Stearns

The Sinking-Fund Method used in connection with value new is, in the judgment of the Committee, equitable, as will be seen by reference to page 72 of its report, where it says: *"The Sinking-Fund Method* assumes that returns are to be based on the full value of an item of property." Mr. Swain also supports this view.

If the return for the use of capital is reckoned at 7%, the rate-payers, under the Sinking-Fund Method, would pay $7.00 + $3.02 = $10.02, each year of the life of this item of property for the use and amortization of the capital invested in it. Under the Straight-Line Method, if value new is used, they would be required to pay instead, for the same purposes, $12.00 each year. Is it not "confusing" to claim that $10.02 per year is equitable as a return for these purposes, and that $12.00 is also equitable? If the $10.02 is an equitable amount, as both Mr. Swain and the Committee agree, then the $12.00 represents each year a confiscation of the property of the rate-payers equal to practically 2% of the cost of this item of property.

The Straight-Line Method becomes equitable as between the rate-payer and the corporation only when the valuation of the item of property is reduced from year to year by the amount which the investment in that particular item of property has been repaid by the rate-payers. This does not mean that the investor in the original property will not continue to receive returns on the full amount of his investment, because the part of the investment which is returned to him through the depreciation allowances can be reinvested just as the investor in a note, when a part of the principal has been repaid to him, can reinvest the money so received and continue to receive interest on the full amount of his principal, although not from the holder of the original note.

The inequitable results obtained when using value new with the Straight-Line Method also obtain when using such value with the Equal-Annual-Payment Method, but the amount confiscated from the rate-payer in the latter case is not as large as when the comparison is made with the Straight-Line Method.

Mr. Swain, referring to Table 5 in the Addendum to the report, quotes the statement of the Committee that:

> "It would be grossly unjust to the rate-payers to permit the owner of the property, under the conditions presented, to earn dividends, not only on the $100 000 which he has invested, but also on the additional $117 609 contributed by the rate-payers, and yet this would be the result of using value new in connection with the Equal-Annual-Payment Method of providing for depreciation."

Mr. Stearns.

He then makes this statement:

"The speaker considers it entirely incorrect, with the understanding that the company must renew an item, when worn out, at its own expense without increase of capital. It is entitled to earn a fair return on the items in the last column plus an original depreciation allowance, and at the end of the tenth year, under these circumstances, it will have earned enough to enable it to replace the original plant at its own expense, and will have accumulating funds which will replace the later investments when they require replacement."

An analysis of his statement is in order:

The example given in Table 5 is that of a new plant costing $100 000, having a 10-year life, with the earnings for depreciation invested in additional plant. The total amount of capital invested by the owner from the start to the end of the tenth year is $100 000, but, on account of earnings for depreciation under the Equal-Annual-Payment Method invested in additions to the property, the total value new of the plant increases year by year from $100 000 at the beginning to $217 609 at the end of the ninth year.

Mr. Swain contends that the company is entitled to earn a fair return on the items in the last column—that is, on the value new of all the property, including the part paid for by earnings for depreciation—plus a depreciation allowance.

If, for the purpose of illustration, 7% were to be assumed as a proper annual return for the use of capital, a return of $7 000 each year for such use would meet all the requirements of equity. If, instead of taking 7% of the original investment, the property paid for by contributions from the rate-payers is also included, and all is valued as if new, the 7% per annum would amount to the following sums:

Year.	7% return.
1st	$7 000
2d	7 507
3d	8 085
4th	8 747
5th	9 502
6th	10 365
7th	11 350
8th	12 477
9th	13 763
10th	15 233
11th	16 911
12th	18 339

This tabulation shows that 7% of the value new would give a return of $15 233 in the tenth year, which would be 15.2% on the actual investment by the owner of the property.

Mr. Stearns.

The illustration assumes that additions to the property would be built out of earnings to the extent that the earnings sufficed for this purpose, thus deferring to the same extent the necessity for new capital. As a result, it would be necessary to supply $100 000 of new capital at the end of the tenth year, when, by the assumption, the original property would be replaced, and $7 238 of new capital at the end of the next year, to replace the property built out of earnings at the end of the first year.

Strong objection has been raised by Mr. Swain and others to the suggestion that new capital may be used for renewals.

It would obviously be wrong to use new capital for this purpose if the additions purchased with the rate-payers' contributions for depreciation had been capitalized, as the capital account would be unduly swelled by so doing; but, where the increase of capital has been deferred by paying for additions out of earnings for depreciation, and, as a consequence, new capital is necessary to pay for renewals, the method is not inequitable.

The depreciation allowances invested in additions may represent a depreciation reserve as well as when invested in a fund, and, as a matter of accounting, it is feasible to draw from the depreciation reserve, however it may be invested, for making renewals, but, as a matter of fact and not of accounting, the money thus invested in additions is not available for renewals, but new money must be provided.

Reverting to the table under consideration, it will be seen that if the depreciation allowances invested in additions to the property are considered to be a depreciation reserve, they are sufficient at all times to maintain the investment intact and to pay for the renewal of the property when it reaches the end of its life. Therefore, earnings based on value new, over and above 7% on the amount of the actual investment by the owner of the property, represent a surplus which is not needed for the renewal of the property.

In the first 10 years alone, the accumulated surplus, using 5% compound interest, would amount to $38 308, or about three-eighths of the original investment, and this would be the measure of the confiscation of the property of the rate-payers by using value new in connection with the Equal-Annual-Payment Method of depreciation.

At several places in Mr. Swain's discussion he admits that the combined return for the use of capital and for the depreciation allowance, by the method recommended by the Committee, is fair when the rate of interest used in computing the depreciation allowance is the same as the rate of return for the use of capital. It would be difficult for him to do otherwise than to admit this, because the rates determined by the Committee's Equal-Annual-Payment Method, using the depreciated value of the property as the basis, are identical with

Mr. Stearns.

the rates under corresponding conditions by the Sinking-Fund Method, using value new as the basis.

It is gratifying to have even this admission, because it shows that the use of the depreciated value of property is equitable under some conditions by the Committee's method. This being the case, how can it also be equitable to claim the much higher rates resulting from the use of value new?

Mr. Swain makes the claim that where the rate of interest used in computing the depreciation allowances is less than the rate of return on capital, the property of the stockholder would be confiscated. This claim is not a valid one.

The Committee's plan, as illustrated on page 34 of its report, provides depreciation allowances for amortizing items of property equal to 100% of their value, and a return at the assumed rate on all the investment in the item of property which has not been repaid by the rate-payers. The method, therefore, has incorporated in it all that is necessary to meet the fundamental equitable principles laid down by the Committee.

It is true that Column 7 of the table on page 34 indicates decreasing rates as the property grows older, but it does not follow that decreasing rates are inequitable to the owner of the property. If they were, the Straight-Line Method of depreciation would be especially inequitable, as will be seen by the rapid decrease in rates indicated by Column 7 of the table on page 40.

The fundamental difficulty with Mr. Swain's discussion of this subject seems to be his failure to recognize the difference between sinking-fund payments, which must be invested for the benefit of the sinking fund in order to complete it when an item of property reaches the end of its life, and depreciation allowances, like those provided by the Equal-Annual-Payment and Straight-Line Methods, which are a repayment of a part of the investment in the item of property and can be reinvested where they also will earn income for the benefit of the stockholder. When thus reinvested, whether in a fund or in the property, they keep the investment of the stockholder at all times intact and earning returns. No property of the stockholder is confiscated because of the transfer of a part of his investment from one item of property to another, or temporarily to a fund. The continuous ignoring of the returns from such reinvestment of the money returned as depreciation allowances appears to account for much of his adverse criticism.

Toward the latter part of his discussion, Mr. Swain offers an illustration to "make clear the fact that to take the cost-of-reproduction method, using the value-new-less-depreciation, may, in some cases, mean confiscation". He takes as an illustration a public utility property which is assumed not to need expenditures for renewals for

Mr. Stearns.

the first 10 years, and assumes that the amount earned above operating expenses and taxes varies "from 5% in the first year to 12% in the tenth and subsequent years". It is also assumed "that the depreciation is calculated on the Straight-Line Method, taking a life of 25 years, or 4% per annum". The further assumption is made that the original records of this property have been destroyed and that an appraisal is to be made at the end of the tenth year.

He adds:

"The cost-of-reproduction method is used and shows a cost-of-reproduction-new equal to $1 000 000; but the commission says we must take the depreciated value and the depreciation is about 40%, so that as a basis for earnings, the value of the property is only $600 000. To this we may add the 12% in the renewal fund, or $120 000, making a total of $720 000."

He concludes:

"The value made on the basis of cost-of-reproduction-new-less-depreciation would confiscate the property of the stockholders, which was selling in the markets at $1 200 000 and justified that value, and now becomes worth only about $800 000, or perhaps less. If this is not confiscation, then the speaker does not know what confiscation is."

His Table 24, extended so as to cover the whole 25 years, is reproduced as Table 30.

TABLE 30.

Year of operation.	Percentage on investment earned for distribution to investors and for replacements and renewals.	Percentage paid to investors.	Percentage remaining for replacements and renewals.	Actual depreciation in percentage.

25th	12.00	8.00	4.00	4

Mr. Stearns.

It is "confusing" and "misleading" to have presented the matter in this way, because there is a complete omission of the item of development expense. Mr. Swain evidently believes that this expense should be added in making a valuation, because he gives a general endorsement of the conclusions of the Committee in all matters except those relating to depreciation, and these conclusions included a provision for development expense, and because he has stated in his discussion that "if there should be a lack of a fair return in early years, any such deficiency would be included under cost of developing the business, and in subsequent years a return would be allowed on this also".

According to Mr. Swain's assumptions, 12% is a fair return for the use and amortization of capital, and on this basis the deficiency of earnings in the first year would be 7%, in the second year, 6.25%, and so on, until the ninth year, when the deficiency would be 0.80%, with no deficiency thereafter. The sum of these deficiencies amounts to 35.5% of the original value of the property, and, with accumulations at 5% per annum compounded annually, would amount at the end of the tenth year to 48.6 per cent.

Assuming, as he has done, that the original cost of the property was $1 000 000, and that the reproduction-cost-new would also be $1 000 000, the reproduction-cost-new with the addition of the development expense, therefore, would be $1 486 000.

Of this reproduction cost, $111 000 would be on account of the deficiency in the amount paid to investors, and $375 000 on account of the deficiency in the sum for amortizing the property.

If the property continued to earn 8% on the original cost for distribution to stockholders for the remaining 16 years of its life, and 4% of the original cost as a depreciation allowance, the depreciation fund, including the sum to which the company would be entitled as a development expense under the foregoing assumptions, with interest at 5% compounded annually, would amount at the end of the twenty-fifth year to $1 909 000 to amortize property costing $1 000 000. This is another illustration of the confiscatory character of the Straight-Line Method of depreciation when used in connection with value new—confiscatory of the property of the public.

It is not surprising, in view of such a result, that Mr. Swain states that the Sinking-Fund Method is more favorable to the public. The illustration, however, does not warrant his additional statement that it is equally favorable to the corporation.

If, instead of considering the use of value new, the depreciated value of the property is taken, and, as suggested by Mr. Swain, an appraisal is to be made at the end of the tenth year, the cost of reproduction new is $1 000 000. From this would be deducted the total amount of depreciation by the Straight-Line Method, equal to 40%, giving, as the depreciated value of the property, $600 000. To this

Mr. Stearns.

would be added the 12% in the depreciation fund plus interest, amounting in all to $128 000, and the development expense computed on the basis set forth in the table, amounting at the end of the tenth year to $486 000, making a total of $1 214 000 for a property which originally cost $1 000 000.

This looks very much like confiscation, but it is not the confiscation of the property of the stockholders, as claimed by Mr. Swain.

The enormous development expense in this case is due to two assumptions: First, that such a property is entitled to earn annually 8% of its original cost; second, to the use of the Straight-Line Method of depreciation in connection with value new.

A property of this kind is usually financed for a sum equal to at least one-half of its cost by the issue of bonds, which, in a case like that cited, could be sold on a 6% basis, and, with 8% return on the full value of the property, the stock would pay 10% to the stockholders.

For a 25-year property, if value new is to be used, the Sinking-Fund tables, using a 5% basis, give the proper amount to be earned annually on account of depreciation. This proper amount is 2.1 per cent. The annual depreciation charge of 4%, assumed by Mr. Swain, therefore, represents an excess of 1.9% annually on the full value of the property, either for distribution to the stockholders or for the formation of a surplus. If distributed to the stockholders, where the stock represents one-half of the value of the property, this would mean an addition of 3.8% to the 10%, making 13.8% available for dividends under the proposed assumptions.

If the excessive sums earned for depreciation by using the Straight-Line Method in connection with value new were not distributed to the stockholders, but were retained in a fund, they would amount at the end of the twenty-fifth year to $909 000, corresponding to the surplus already stated.

Mr. Swain's illustration will next be presented in a modified form, so as to make it more rational, and the Equal-Annual-Payment Method of the Committee will be used for computing depreciation.

It does not seem to be in accordance with public policy that the percentage paid to investors should be so large that a property costing $1 000 000 would be "bought and sold between investors on the basis of $1 200 000". Money could be obtained without doubt under such circumstances as those represented by one-half bonds earning 6% and one-half stock earning 8%, making the annual income on the whole value of the property 7%, and this amount will be used in place of the 8% in the previous illustration.

Table 31 covers 10 years, the same as Mr. Swain's Table 24. The percentage earned for the 10 years is copied from his table. The percentage paid to investors is the same in the first 3 years, and then 7%, instead of the larger sum. The percentage remaining for replace-

Mr. Stearns.

ments and renewals amounts in the 10 years to 18.25 in Table 31, as against 12% in Table 24. The total amount of depreciation, using the Equal-Annual-Payment Method on a 5% basis, is 26.37%, in place of the 40% in Table 24. Table 31 shows that there would be a deficiency of earnings in the first 7 years and a surplus in the next 3 years. The development expense, assuming it to be the deficiency of earnings, including 5% interest, would amount to $187 000 at the end of the seventh year.

TABLE 31.

10th	12.00	7.00	5.00	3.25
Total for 10-year period.	84.50	66.25	18.25	26.37

If a valuation were to be made, as assumed by Mr. Swain, at the end of the tenth year, the value new would be, as he has stated, $1 000 000. The total depreciation to the end of the tenth year would be $264 000, leaving as the depreciated value of the property $736 000. To this should be added the 18.25% in the depreciation reserve plus interest, amounting in all to $200 000, and the development expense, assuming it to be the same as at the end of the seventh year, $187 000, making a total of $1 123 000 for a property which originally cost $1 000 000.

The adoption in this case of a more reasonable rate of return and a more reasonable depreciation allowance results in a more reasonable development expense and a more reasonable reproduction cost of the property. The reproduction cost, however, is still $123 000 more than the original cost, although so large an excess would not be warranted by the deficiency of dividends during the early years of the life of the property. There is still a confiscation of the property of the ratepayers, and this is due mainly to the assumption that during the first 10 years the earnings are based on value new and not on the depreciated value of the property, as they should be when this method of depreciation is used.

If an illustration had been presented in which the earnings were based on the depreciated value of the property, instead of on value new,

Mr. Stearns.

and if 7% compound interest were used in computing the depreciation allowance, the development expense and the accumulation of the depreciation reserve, the reproduction value of the property, including the depreciation reserve and the development expense at the end of the tenth year, would have been only enough more than $1 000 000 to compensate for the net deficiency of dividends during the 10-year period. Under such circumstances, there would be no confiscation of the property of either the corporation or the rate-payer.

The Committee holds the view that the appreciation of land, and of some other items of property which appreciate in value, is closely related to the depreciation in the value of the structural property, and that, if the public makes good to the corporation the loss of value of the portions of the property which in the course of events are practically sure to depreciate, the corporation should also make good to the public the increase in value of the portions of the property which are practically sure to appreciate.

Mr. Swain takes the ground that an appreciation in land is an appreciation in price. He mentions two kinds of depreciation, one due to wear and tear and approaching obsolescence and the other which may result from the smaller cost of performing work, and states that the appreciation in land should be compared with the depreciation due to the smaller cost of performing work and not to the depreciation caused by wear and tear and approaching obsolescence.

Under existing laws it seems to be necessary to value property at substantially present prices, and the increase or decrease in value, due to changes in the cost of performing work, which, in recent years, has been almost wholly increase, is a risk which the owner of a property under existing conditions is obliged to assume.

In order to obtain equitable results, the cause of a continuing depreciation or appreciation in the value of property is not important. It is the fact that structural property is bound to depreciate which makes it equitable for the public to make good to the corporation annually the amount of such depreciation, and, similarly, the fact that land under most circumstances is bound to appreciate in value which makes it equitable for the corporation to make good to the public the amount of such appreciation.

Owing to a rise in prices, items of property which in time are bound to go out of use owing to wear and tear or obsolescence may be worth more after they have attained a certain age than when new, and, similarly, owing to change in prices, there may be years in which land will not appreciate, but, in the long run, land in a growing community does appreciate in value.

Mr. Swain takes the ground that in appraisals the present value of the property must be taken, and that, if the reproduction cost at present prices means an increase in the value of the property, the corporation is entitled to the increment.

Mr. Stearns.

In this argument, however, he does not take the present value of the perishable property, but the value of such property as it would be if it were new, although it is obvious that an old locomotive, car, or tie has much less real value than a new one. If he were to take the real value of such perishable property, instead of its value new, the same line of reasoning, by which he attempts to show that the corporation should not be required to make good to the public the amount of the appreciation in land, might be used to show that the public should not be required to make good to the corporation the depreciation in the value of the perishable property.

The most common argument against the Committee's position that equity requires the owner of a public service property to account to the public for the appreciation of land is expressed by C. P. Howard,* M. Am. Soc. C. E. He states that "All other owners of property enjoy this increase as a clear bonus; the unearned increment". Is this a correct statement?

In the case of a public utility, the owner should be permitted to charge rates to reimburse the sums paid for taxes on the land, and, under the views expressed by the Committee, he is entitled to have a fair return on the fair value of the land as well as on the fair value of any other property.

The private land owner does not have his taxes paid for him and is not entitled to receive from the public a fair annual return on the value of his property. In most cases where the land is vacant he does not receive more than a meager return, if any, and has to depend mainly on the appreciation in the value of the land in order to obtain finally a fair return.

If it is correct to infer that because private owners enjoy an increase in the value of land, the owner of a public utility should likewise enjoy such increase, is it not equally correct to infer that if the private owner of a building on the land has to stand the loss due to the decrease in value of the building as it grows older, the owner of the public utility should likewise stand the loss due to the decrease in value of a building owned by him, and not claim that the public should pay him a depreciation allowance to compensate him for such loss?

To revert once more to Mr. Swain's discussion, he claims that in the case where the cost of constructing a property is known, the cost new is an admittedly correct method, and that as the cost-of-reproduction-new is a substitute for cost new, when the latter cannot be ascertained, it also should be used instead of the depreciated value.

If cost new were an admittedly correct method, then the deduction made by Mr. Swain would be logical, but, in the speaker's opinion, it is not a correct method when a method of providing for depreciation is used which returns to the owner of the property the full value of each item during its life.

STEEL STRESSES IN FLAT SLABS.

Discussion.*

By Messrs. L. J. Mensch, W. K. Hatt, and H. T. Eddy.†

Mr. Mensch.

L. J. Mensch, M. Am. Soc. C. E. (by letter).—This paper appears to the writer to be a defense of, and a propaganda for, the so-called mushroom type of flat floor construction.

The author seems to be quite satisfied that mushroom floors with a notoriously deficient quantity of steel reinforcement are safe and proper constructions. This is a debatable question, with reference to the factor of safety required. In some constructions there is a factor of safety of a little more than 1, as in foundations, retaining walls, dams, bridge abutments, etc., in fact, where the carrying capacity and cohesion of the ground is to be considered. In other cases a factor of safety of hardly 2 is often, knowingly or unknowingly, adopted, as in columns, whether of steel, brick, or concrete, especially in outside columns and those which are eccentrically loaded, also in roof trusses, common brick walls in buildings, etc.

The numerous cases where such low factors of safety are found may blind an engineer and make him believe that he is as well justified in adopting a similar factor of safety in flat slab construction. On the other hand, engineers are accustomed to allow a factor of safety of 3 in steel-girder constructions, and the general public demands a factor of safety of at least 4 in reinforced concrete construction, on account of its novelty and its greater uncertainty in erection.

The writer claims that a large percentage of the examples cited by the author have a factor of safety of a trifle more or less than 2, and that his formulas simply accommodate the extensometer tests of these slabs. Extensometer tests do not give any indication of the real strength of a slab, which is reinforced by light bars and to such low amounts as ¼ per cent. The extensometer gives the elongation in a

* Continued from March, 1914, *Proceedings*.

† Author's closure.

Mr. Mensch.

length of generally 8 in. of steel bars embedded in concrete. Where the surrounding concrete is not cracked in the 8 in., the extension obtained by the extensometer, in inches per inch of length, multiplied by the modulus of elasticity of the steel, generally taken at 30 000 000, will give the steel fiber stress, but no correct idea of the interior resisting moment, because the tensile strength of the concrete is disregarded. Assume, however, that there is a crack in the concrete between the contact points of the extensometer, then the stress is transferred by shear and by the bond of concrete and steel to the steel bar in the neighborhood of the crack, and the bar is stressed considerably higher at the crack than at points farther from it.

For an illustration, assume that the reinforcement consists of $\frac{3}{4}$-in. round bars, 6 in. from center to center, that the crack in the concrete is 1 in. deep, and that the tensile strength of the concrete is 200 lb. per sq. in. The surface of a $\frac{3}{4}$-in. bar per lin. in. is 1.18 sq. in., and its cross-section is 0.11 sq. in. The original strength of a concrete section, 6 in. wide and 1 in. deep, is $6 \times 200 = 1\,200$ lb., and, assuming a bond stress of 400 lb. per sq. in., or 472 lb. per lin. in. of $\frac{3}{4}$-in. bar, it will require a length of 3 in. on each side of the crack to transmit the original strength of the cracked portion of the concrete into the bar. This additional stress in the steel fibers amounts to $1\,200 \div 0.11 = 10\,900$ lb. per sq. in., and, for determining the elongation of the bar we have to assume that it acts only on an average of 3 in., though the extensometer measures on 8 in.; hence the stresses obtained by extensometer readings are in this particular case only three-eighths of the actual stresses. In other words, when one tries to judge, from extensometer readings, the distribution of the exterior bending moments, or their equivalent, the interior resisting moments, one is likely to under-estimate the value of the exterior bending moments 50% and more, due to the neglect of the tensile stresses of the concrete.

The fact that extensometer readings do not permit any correct conclusions as to the interior resisting moment, or the factor of safety of the slab, is indisputably proved, by tests made by Richard L. Humphrey, M. Am. Soc. C. E.* In that investigation there were 336 beams, 13 ft. long, 8 by 11 in. in cross-section, and they were tested on a 12-ft. span by two equal loads at the one-third points. The reinforcement throughout consisted of $\frac{1}{2}$-in. bars, having a yield point of approximately 40 000 lb. The number of bars varied from two to eight, corresponding to a percentage of $\frac{1}{2}$ to 2. The mixture of the concrete was 1:2:4 by volume, and the tests were made when the beams were 4, 13, 26, and 52 weeks old. In every beam tested there were careful readings of the deformations, both of the top fibers and of the steel fibers, for stages of loadings of from 500 to 1 000 lb. up to the ultimate load.

Mr. Mensch.

In Table 14, taken from Technologic Paper No. 2, it will be noticed that Beam No. 337 failed at a total load of 6 740 lb. At a load of 3 500 lb., which is more than one-half of the ultimate load, the extensometer reading of the steel fiber was $\frac{156}{1\,000\,000}$ in. per in.; or, multiplying this extension by 30 000 000, we obtain a stress of only 4 680 lb. It is well to keep in mind that the extensometer reading gives such a low stress when the factor of safety is less than 2. Similarily, we find that at a load of 4 500 lb., which is two-thirds of the ultimate load, the stress in the steel fibers is 14 160 lb. At 5 000 lb., which is 75% of the ultimate load, the steel fiber stress is only 19 000 lb. per sq. in. Similar conditions may be found in every beam tested, even in those with 2% of reinforcement. One may reasonably expect that the discrepancies will be still greater in flat slab construction, where the percentage of reinforcement is considerably lower than in Beam No. 337, being mostly only $\frac{1}{4}$ to $\frac{1}{3}$ of 1 per cent. One can even imagine the case where, with an insufficient quantity of reinforcement, the slab will break at practically the same load as a non-reinforced slab, where, just before breaking the extensometer would not show a larger extension that 0.0001 in. per in., corresponding to a stress at failure of only 3 000 lb. per sq. in.

In studying the tables it is found that at certain stages a very small increase of the load causes a great change in the extensometer readings, which explains the great discrepancies found by Mr. Eddy in the stresses of adjoining bars or of symmetrical points. The unreliability of extensometer readings for the determination of the interior resisting moment of reinforced concrete beams was discussed by the writer before the Western Society of Engineers in the spring of 1904.*

There is yet another simple indication that the flat slab constructions cited by Mr. Eddy have not the conventional factor of safety, and that is the appearance of cracks at the most dangerous sections, where one would expect to find them at loadings of from one-third to one-half of the ultimate load. From tests of beams reinforced by $\frac{1}{4}$%, it is known that cracks appear at a load which is about three-fourths of the ultimate; and, in slabs reinforced by $\frac{1}{2}$%, at about one-half of the ultimate load.

Mr. Eddy writes:

"Indeed, slab action in general may be described partly as the attempted mechanical superposition of one set of parallel depressions and elevations on another set of similar corrugations at right angle to them. Such sets mutually support each other and give rise to slab action. * * *"

This sounds mysterious, and will not enlighten any one; it only shows that the author does not care to express in a scientific way the

* The *Journal* of the Western Society of Engineers, for 1904, contains a number of tables and diagrams.

real slab action, as has been done, for example, in a masterful way, by the Italian engineer, Danusso,* and by others. Mr. Mensch.

There is no mystery about slab action. It is simply a combination of continuous beams acting in at least two directions, which beams are connected with each other and with the columns, and the deflection in any point is common to at least two beams acting at right angles to each other.

On account of the large sizes of the columns and column heads, and the depression of the floors at the columns, the beams directly connecting the columns, and corresponding to the sides of the squares, have considerably greater stiffness than those parallel to them and nearer the center of the slab, and these beams have a comparatively still greater stiffness than any diagonal beams, with the result that the mechanical action of the whole slab must be nearly identical with the action of a flat slab of a smaller span than the distance from center to center of columns, supported by four wide girders of a depth somewhat greater than the thickness of the slab.

If we omit to take into account the presence of the large columns and column heads, we obtain the case considered by Winkler and Grashof, who assumed the supports of the slab to consist of ideal points, and who found that the bending moment in the center of the span is $\frac{WL}{48}$ and over the columns and side of the square is $\frac{WL}{24}$, when W is the total load on the panel, L is the distance from center to center of columns, and Poisson's ratio is 0.1. The bending moments change only very slightly if other values of Poisson's ratio are assumed. For steel, it is generally found at 0.3, and the moments become $\frac{WL}{26.4}$ and $\frac{WL}{52.8}$, respectively. Returning again to the flat slab as a combination of four wide beams supporting a smaller flat slab, it is only within reason to assume that the wide girders have to carry the same loads as ordinary beams in the case of a flat slab supported by narrow and deep beams.

It is here that one finds a riotous license of figuring by most of the advocates of flat slab constructions. According to most building ordinances and accepted good practice, the bending moments in beams supporting flat slabs must be taken both over the supports and in the center of the beams at not less than $\frac{W}{2} \times \frac{L}{12} \times \frac{3}{2}$ (the latter factor on account of the triangular application of the load over the beam) $= \frac{WL}{16}$, although theory shows that the bending moment in the center of the span is only $\frac{WL}{32}$.

* "Il Cemento," 1912.

Mr. Mensch.

Now, the advocates of the mushroom system are not satisfied to figure the bending moment in the center of the side beams as the theoretical moment, which is only one-half of the moment any engineer is allowed to figure when he adopts common girder construction; they go still further, and claim the right (according to Mr. Eddy's Equation 34) to figure this moment as $\frac{WL}{175}$, which is one-tenth of the moment required by the building ordinances. There we hear again that they must be right or their constructions would fail at the first application of the design load, and that they are right because the extensometer readings bear them out. The writer has shown how erroneous are the results obtained by extensometer readings; it remains yet to prove that the real bending moments in the center of the side beams are less than are required by the building ordinances, otherwise their structures actually would not stand up.

In flat slabs supported by continuous girders of slightly greater stiffness than the slab, the Italian engineer, Danusso, has shown that the load of the slab is distributed nearly uniformly over the girders, instead of with the triangular distribution found for very stiff beams; hence the bending moments for a beam supporting two adjoining panels are theoretically $\frac{WL}{24}$ and $\frac{WL}{48}$, at the supports and the center, respectively. Engineers need not be surprised that the bending moments for the stiffer side beams are just as large as those given by Grashof for the whole width of the slab. This case happens very often in ordinary girder and joist construction. Assume, for example, a flat slab supported by parallel walls, 20 ft. from center to center. If this distance is spanned by a simple slab, the bending moment is $\frac{WL}{8}$. As a rule, it is cheaper to provide girders of 20 ft. span and, say, 10 ft. from center to center, which girders must be figured for a moment of $\frac{WL}{8}$, and the slabs between the girders must be figured for another bending moment. Hence the sum of all bending moments is larger than the original moment $\frac{WL}{8}$, yet the cost of the construction is generally less.

In continuous beams which are of larger moment of inertia near the supports than in the center, such as is the case with the large columns and column heads used, it is known, also, that the moments at the supports become larger and those in the center of the span become smaller; taking also into consideration the fact that the span of the side beams may be safely diminished by one-half of the diameter of the columns, the moments of $\frac{WL}{24}$ and $\frac{WL}{48}$ become in most cases

cited by Mr. Eddy, where no depression in the floor is used, $\frac{WL}{24.4}$ and $\frac{WL}{62}$; and, where a depression is used, they become $\frac{WL}{22.2}$ and $\frac{WL}{92}$. Hence, in the most favorable case, giving the mushroom system all the advantages of continuous action, such as is not adopted by any responsible designer in any other class of work, neglecting at the same time all possible settlements, Mr. Eddy advises the use of a bending moment of one-half of what it can possibly be, which readily explains the low factor of safety. Mr. Mensch.

The advocates of the mushroom system may claim that the diagonal beams help to support a great portion of the load which the side beams are assumed to carry. Mr. Eddy, however, admits that the stresses in the center of the diagonal beams are generally found to be one-half as great as those in the side beams; this, together with the fact that the span of the diagonal beams is 1.41 times that of the side beams, permits the conclusion that a diagonal beam supports only one-quarter of the load of a side beam, and, in fact, simply transmits the loads from the interior of the panel to the side beams.

Mr. Eddy advises calculating the diagonal beams in the center for a moment of about $\frac{WL}{250}$, which does not seem to be sufficient, even for the simple transmission of the loads to the side beams. Granting that the width of the side beams may be assumed to be four-tenths of the span from center to center of columns, the width of the interior slab is six-tenths of L and the bending moment per linear foot of the interior slab, according to most building ordinances, must be figured as $\frac{w\left(\frac{6}{10}L\right)^2}{24} = \frac{wL^2}{66.67}$, while $\frac{WL}{250}$ per diagonal beam corresponds to $\frac{wL^2}{150}$ per lin. ft. of the interior slab.

It is remarkable that Mr. Eddy overlooked the fact that the distance between the points of inflection on the sides of the squares of several of the tests cited by him were found to be from $0.5L$ to $0.55L$. According to his own statements, the bending moment must be larger in the center of the sides than $\frac{w.(0.5\,L)^2}{8}$ and $\frac{w.(0.55\,L)^2}{8}$, or $\frac{w.L^2}{32}$ and $\frac{w.L^2}{27}$, respectively, while his moment of $\frac{W.L^2}{175}$ corresponds to $\frac{w.L^2}{70}$.

The advocates of many flat slab systems declare that the common beam theory does not apply to flat slabs. The writer has never seen a similar statement in the works of St. Venant, Winkler, Grashof,

Mr. Mensch.

Föppl, or Müller-Breslau, who, in much more difficult problems than this, applied only the common beam theory, and in particular, the case of flat slabs was solved by Winkler and Grashof by that theory. There is yet one defense open to the advocates of the mushroom system, and that is the mystic influence of Poisson's ratio, but Mr. Eddy himself states that, on account of bending moments of opposite signs acting at right angles at the center of the side beams, the stresses there are larger than in a common beam; hence he can use it only for a defense of the low moments he assumes over the columns, and he claims that Poisson's ratio must be assumed as one-half. This, however, is a mechanical impossibility, clearly excluded by Grashof, as a simple change in shape without any change in the distance of the molecules is identical with a Poisson's ratio of one-half. Over the columns we have the most unfavorable combination of maximum bending moment and maximum shear acting together in the same section, and Grashof advised, even in the case of steel, reducing the stresses over the columns by 20 per cent. Besides, near the ultimate load, the concrete is cracked in every direction around the columns, and the steel bars will hardly be benefited by stresses acting in two directions, although the concrete in compression may be helped considerably. The percentage of reinforcement being low, an increase of the compressive stress of the concrete of 50% will benefit the internal resisting moment less than 5 per cent.

Mr. Eddy considers only the case of all panels loaded, which is a more favorable one for the center of all beams than that of a single panel, or two panels loaded, and extensometer tests clearly bear this out. In the discussion of a former paper on this subject,* the writer has shown that in the latter case the slab and the supporting columns and the columns above the slab form an arch construction in which the columns are very highly strained by the negative moments at the supports, and that the negative moments in the adjoining panels are very small when the columns have a larger moment of inertia than the slab. These conclusions were proved indisputably by the tests recently made by Mr. W. A. Slater, of the University of Illinois, on a new factory building of the Shredded Wheat Company, at Niagara Falls, N. Y. Mr. Slater presented the results of the test in a paper before the meeting of the American Concrete Institute in Chicago, in February, 1914. Although the floors were tested to only 1½ times the total dead and live load, numerous fine cracks appeared, and the extensometer indicated steel stresses of 15 000 lb. per sq. in. in the slab and additional compressive stresses in the columns, due to the loading of panels on one side of the columns, of 400 lb. per sq. in.

Mr. Eddy declares that the drops in the floors are unsightly, bulky,

* *Proceedings*, Am. Soc. C. E., for August, 1913.

Mr. Mensch.

and unnecessary, and prefers the mushroom type, where the depression of the floor is omitted and replaced by a magic steel ring in the neutral axis of the slab. That this advocates very poor construction, not countenanced by any reputable engineer, may be seen from the detail of the slab of the Northwestern Glass Company's Building, cited by Mr. Eddy. The column caps scale 36 in. in diameter, the dead weight of the floor is 120 lb. per sq. ft., the live load is 400 lb. per sq. ft., and the total load of a panel supported by one column is $16 \times 17 \times 520 = 141\,440$ lb. The floor slab is 8 in. thick, and the sectional area of the slab in shear around the cap equals $36 \times 3.14 \times 8 = 904$ sq. in., or a shear of $141\,440 \div 904 = 155$ lb. per sq. in. of the total section, or of about 220 lb. per sq. in. for a section of the depth of *jd*. Most building ordinances allow only a shear of 125 lb. per sq. in. on the section of a depth of *jd*, and prescribe the use of bent-up bars and stirrups at the section of great shear; on the other hand, the advocates of the mushroom system and their imitators take another license to step over ordinances and sober reasoning, allow a high shear, and no scientific reinforcement for shear whatsoever.

When called to task for allowing such a high shearing stress, these experts defend it by saying that only "punching shear" is acting. The writer does not know that "punching shear" is a term common in engineering, but, if it means anything, it must mean pure shear, like that in a true punching operation, when practically no bending stresses are acting on the material which is being punched. We have shown before that around the columns the maximum moment and the maximum shear are acting together, and that the stresses must be reduced and not increased at that section.

A great many thoughtless and entirely erroneous statements in reference to flat slabs may be found in most articles published on this subject in current engineering literature, and an example is Table 15.

TABLE 15.

No.	Method.	Thickness of slab, in inches.	Steel per panel, in pounds.
1	Cantilever	8	2 189
2	Turneaure and Maurer	12	1 931
3	Grashof	8	784
4	Mensch	8	2 120
5	Turner	8	549
6	McMillan	8	1 084
7	Brayton	8½	1 900

This table is from a discussion by A. W. Buel, M. Am. Soc. C. E., in *Proceedings*, Am. Soc. C. E., for August, 1913.

From Table 15 it would appear that a flat slab, of 20 ft. span and a thickness of 8 in., contains per panel 784 lb. of reinforcing steel, if designed according to Grashof for a total dead and live load of 300

Mr. Mensch.

lb. per sq. ft. The writer has shown that Grashof's moments for the center and the sides of the square are $\frac{W.L}{48}$ and $\frac{W.L}{24}$, $W = 400 \times 300 = 120\,000$ lb., $L = 20$ ft., and $\frac{W.L}{48} = 50\,000$ ft-lb. and $\frac{W.L}{24} = 100\,000$ ft-lb. for the entire width of the panel, or per lin. ft., 2 500 ft-lb. and 5 000 ft-lb., respectively.

Adopting an allowable fiber stress for the reinforcing steel of 13 000 lb. (although it is too high for mild steel where a factor of safety of 4 is desired), and assuming the distance of center of reinforcing to the compression face as 7 in. (which is a trifle too small for the center of the slab and considerably too large for the sides of the square), we find that the sectional area of the reinforcement for a bending moment of 2 500 ft-lb. per lin. ft. in the center of the slab is 0.33 sq. in. and double the area is required at the sides of the square.

Where the negative reinforcement is obtained by bending all bars up at the quarter point, and continuing the rods to the quarter point in the adjacent panels, the weight of the steel reinforcement per linear foot of the panel in one direction is $0.33 \times 3.4 \times (20 + 2 \times 5) = 34$ lb., and for the entire panel in both directinos $34 \times 20 \times 2 = 1\,360$ lb. It is very poor practice to bend up all bars; this would not be permissible in any girder construction on account of reversal of moments which may occur by settlements and unfavorable loadings in other panels. Assuming that one-third of the bars are straight and extend only 1 ft. beyond the center line at each end, and that, therefore, extra rods are required on top over the sides of the square, we find that at least 340 lb. of additional reinforcement must be placed in each panel, or a total of 1 700 lb.

Hence, according to Grashof, it requires in continuous panels at least three times as much steel as used in the Turner system, provided that the statement in Table 15 in regard to the Turner system is correct. Inasmuch as we have to design for the case of only two panels loaded side by side, it requires a great deal more reinforcing than the 1 700 lb., not counting the additional reinforcing which is absolutely necessary in the columns to overcome the bending stresses produced by one-sided loadings.

The writer begs not to be misunderstood as being an opponent of flat slab constructions. He thinks he was the first to use flat slabs on a large scale, for he built two slabs, 100 ft. square, at the new plant of the Proctor and Gamble Company's soap works at Armourdale, Kans., in 1903, and has built many others since. He protests, however, when engineers and contractors (who, as a rule, have all to gain and nothing to lose), represent by versatile agents that flat floor constructions, of designs as advocated by Dr. Eddy, are as good as, or

Mr. Mensch.

better than, girder constructions, which actually have a factor of safety of 4 or more, if they are designed according to the Chicago Building ordinance, for example, and if they are constructed right. No wonder that they can show to unsuspecting architects and owners a great saving over all other designs, and, being able to mention a great number of examples of buildings which did not fall down (having a factor of safety of about 2), are believed to be by the owners and architects very wizards in the art of reinforced concrete construction. It is true, however, that flat slabs show a slight saving (even if they are designed for a factor of safety of 4) over girder construction of the same factor of safety. The writer has not the reputation of wasting any material in the structures which he designs and builds; being a contractor, it would simply diminish his profits, yet he can mention a number of examples which were actually loaded with about four times the total dead and live load without breaking down.

In December, 1902, a girder in the Salvation Army Building, in Cleveland, of 24 ft. span and designed for a load of 100 lb. per sq. ft., was tested with 100 000 lb., which is about $3\frac{1}{2}$ times the total dead and live load. The girder showed some cracks, but no indication of a near failure, and the permanent deflection was $\frac{1}{4}$ in.

In the spring of 1905 the writer built a furniture storage house for the Brown Transfer and Storage Company, at St. Joseph, Mo. The structure was designed for a live load of 100 lb. per sq. ft. In the fall of 1905, when the writer started another building for the same company, he found that the building was rented to the Parker Grocery Company, which lost its own building by fire, and was loaded all over to the ceiling with canned goods weighing at least 600 lb. per sq. ft., so that both floors and columns withstood nearly four times the total dead and live loads.

In 1905 the writer designed and constructed a building for the Seng Company, Dayton Street, Chicago. The building was designed, according to the new Chicago ordinance for reinforced concrete, for a live load of 100 lb. per sq. ft. On account of some failures of concrete buildings all over the country at that time the owner refused payment on the building as the work progressed until such time as the writer could prove that the building had a factor of safety of 4. In the presence of a great number of engineers and architects, the writer tested one panel, only one month old, in December, 1905, with 600 lb. per sq. ft. The girders and slabs deflected and cracked considerably, but did not fail under the load, which remained there 24 hours. The permanent deflection was only $\frac{1}{8}$ in.

These examples should suffice to show that girder and slab constructions, correctly designed and built, have a factor of safety of at least 4, and there is no question that flat slab constructions can be made as safe as any others, but the writer claims that flat slabs designed according to Mr. Eddy's formula have only a factor of safety of 2, under the most favorable circumstances.

Mr. Hatt. W. K. HATT, M. AM. SOC. C. E. (by letter).—The recent extension of testing operations to completed structures has shown, what many have known, that reinforced concrete structures carry their working loads in service by the help of tensile stresses in the concrete. The stresses in the steel may not be more than one-half or one-third of those which would be calculated by the ordinary formulas, which neglect these tensile stresses.

For the purpose of standardizing design, and as a matter of safety, the conventions of the building codes properly omit these tensile stresses. They cannot be ignored, however, when the complete action of the structure is to be accounted for under working loads.

The variability of the quality of concrete not only makes it desirable to omit these tensile stresses in calculations for design, but it also renders the steel stresses, which are measured in tests of buildings, a very uncertain factor; that is to say, the measured stresses in the steel depend very largely on the quality of the concrete. Good concrete may relieve the steel of the greater part of its expected moment of resistance.

It follows, therefore, that, in judging the mechanical action of any type of structure, more attention should be paid to the measured compressive stresses in the concrete than to the measured stresses in the steel.

Mr. Eddy. H. T. EDDY, ESQ. (by letter).—Mr. Godfrey has taken the opportunity to repeat his objections and warnings against the use of flat slabs, and especially to insist that, whatever may be the true theory of an interior panel of a flat slab of indefinite extent and uniformly loaded, that theory cannot apply either to a single loaded panel or to an exterior panel, and, further, that the theory under discussion involves reliance on direct tension stresses in the concrete.

The full treatment of these questions involves a multitude of details, including bending moments in columns, cantilever action, direct and indirect stresses in concrete, bond shear, shock due to moving loads, the conditions under which beam action prevails over slab action, etc., etc. These questions and criticisms have been raised before by Mr. Godfrey, in connection with the discussion of Mr. Nichols' paper,* and have been answered in detail. Ultimately, dependence must be placed on the facts as they appear in test and practice, rather than on *ex cathedra* statements of what must occur as a consequence of views held on theoretical questions.

The crux of the entire matter seems to lie in the question of direct and indirect stresses in concrete, the latter being those called into play by bond shear and the former by bending.

* "Statical Limitations Upon the Steel Requirement in Reinforced Concrete Flat Slab Floors," *Proceedings*, Am. Soc. C. E., for April, 1913.
(This paper has not yet been published in *Transactions*, owing to the failure of the author to close the discussion.)

Mr. Eddy.

The indirect tensile and compressive stresses in the concrete due to bond shear enable the rods of the belts which cross each other to co-act with each other under tension and cause the slab to exhibit effects similar to those measured in flat plates by Poisson's ratio. It is evident that as long as the bond is intact at the surfaces of the rods, the indirect stresses—which necessarily have the same numerical intensity as the bond shear—do not exceed the strength of the concrete, and the mechanism for the same kind of interaction exists in the slab as in the plate. This phenomenon, therefore, must be taken account of in one case as much as in the other. Consequently, the value of K for slabs is inextricably bound up with the question of bond shear and indirect stresses in the concrete in the tensile zone. No general discussion of the numerical value of K will be taken up at this time, other than to remark in passing that, in order that a homogeneous solid may remain of constant volume, it is necessary from geometrical considerations to have $K = 0.5$, a value which undergoes greater or less diminution in case of various actual solids, according to their volumetric elasticity.

Likewise, in order that a material sheet or surface may remain of constant area, it is geometrically necessary that $K = 1$, where K refers to lateral distortion in the plane of the sheet or surface, as it does in a slab, and has nothing to do with changes of thickness of the sheet. For sheets of various materials, this value of K will be diminished according to its areal elasticity in resisting forces tending to stretch it in its plane.

All reinforced concrete construction is based on the effectiveness and reliability of bond shear. Without its action, no beam or slab could endure, but its action in a slab, not only effects all the results it produces in a beam, but must necessarily cause the slab to exhibit additional properties due to the interaction of multiple-way reinforcement consisting of wide belts of rods in contact with each other. In case the belts are made of numerous parallel rods with a spacing comparable to the thickness of the slab, the slab is sufficiently fine-grained to act very much as if it were of uniform texture but formed of some material not the same as either of its constituents.

It is entirely beside the mark for Mr. Godfrey to argue that, because this composite material has in it reinforcing rods, and Poisson's ratio does not apply to rods considered separately, that this ratio, therefore, has no application to a material like a slab of which rods form an integral part by their intimate union with the concrete, just as truly as if the reinforcement were made into a single sheet and combined with the concrete, although, of course, the value of K would not be identical in the two cases.

What the physical and mechanical properties of such a slab may be cannot well be predicted with certainty, although it may be pos-

Mr. Eddy.

sible to give a rational explanation of what experiment may show its new and unforeseen properties to be. Whenever such a slab undergoes flexure which causes it to assume a dish-shaped deformation, the peculiar and unexpected properties appear; but it is just on this question of dish-shaped deformation in a slab that Mr. Godfrey has expressed views least in accordance with the facts.

Suppose, for example, a long building with two rows of columns parallel to the long sides, and panels nearly square, so that there are three tiers of panels lengthwise of the building, one long interior tier being between the two long wall tiers. Now, suppose heavy loads to be placed on three panels of a tier or bay extending across from wall to wall. If the writer understands Mr. Godfrey, he thinks that such an arrangement of loading would produce a critical stress in a mushroom slab much greater than would occur if the loading were removed from either two of the three panels. It might do this were it not for the wall supports and the stiff heads; but in fact the reverse is true. The walls entirely prevent the formation of the ends of any such cylindrical trough across the slab, and the stiff heads and walls will tend to accentuate the hollows parallel to the long walls, rather than those perpendicular to them.

The experimental test on which Mr. Godfrey relies to prove his contention has little or no bearing on the slab question, for similar reasons.

The panes of glass on which he experimented* had no continuous support at the edges, such as a slab has, to say nothing of additional local stiffness at the points of support furnishing at these points moments of resistance several times as great as those found elsewhere. The plates were not clamped to practically immovable supports so as to make them act in a manner at all similar to a floor slab such as that under discussion. Consequently, these plates would not act like a floor slab at all, and the assumption that they would is entirely misleading. As just stated, the behavior of glass plates supported in this manner would be the reverse of the slab, in that the troughs in the one would be accentuated in a direction different from those in the other.

This and other matters in the discussions connected with Mr. Nichols' paper directly controvert the statements of Mr. Godfrey, which he evidently regards as incontrovertible, as he has made these statements a number of times and they have never been controverted, as he says; and all this will occur without contravening any law of Nature.

All engaged in concrete design and construction should be equally desirous, with Mr. Godfrey, that it should be conservative and safe, and also that it be adopted where it can safely be done at a cost so

* *Proceedings*, Am. Soc. C. E., for August, 1913, p. 1361.

moderate as to permit fire-proof in place of combustible construction, as it cannot be if there are unreasonable requirements. Mr. Eddy.

It is not lightly to be assumed that any concern which has been responsible for the design of about two thousand structures of this character without failure, and with inside opportunities for knowing with certainty what can be depended on, and having also enormous financial interests at stake, may not be a good judge of what can and ought to be done in this field.

Mr. Godfrey refers to a paper by the writer entitled "A Comparative Test of Two Full-sized Reinforced-Concrete Flat Slab Panels,"* and tries to convey the impression that the manner of loading and the design of the columns were responsible for the good showing made by the mushroom slab. He states that the test slab was loaded with balancing loads, meaning by that that the load on the over-hang beyond column centers reduced the stress in the central panels so greatly as to make the stresses in the steel small and misleading.

It will be noticed that Mr. Eckles asserts that his experiments showed greatly increased central deflections due to extending the loading into the panels at the sides of the panel tested. These contradictory views cannot both be true.

The truth is that neither of them represents the facts. If there is anything that has been established by numberless load tests of mushroom slabs, it is that in the standard mushroom slab the central deflection and stresses of an interior panel are not affected to any appreciable extent by the loads on surrounding panels. A very small effect has been thought to be discoverable at the centers of panels situated diagonally, but no mutual effect between panels beside each other.

This fact, which would at first sight seem inexplicable, is apparently the result of a close balancing of two opposing effects, *viz.*, any load just outside a panel will have a tendency to lift the center of the panel, but, at the same time, it will tend to increase the deflection of the side belt between it and the center of the panel. Any such deflection at the side belt will have a tendency to increase the deflection at the center of the panel. Whether the lifting or the increase of deflection preponderates depends on the relative rigidities of the belts and the slab and column heads, with the result stated above. Not having at disposal sufficient data in other types of construction to state conclusions with certainty, the writer has refrained from doing so.

The panel tested by Mr. Eckles was at a corner of a slab. It may have been a mushroom slab in general design without having any features of the system in this corner panel beyond one mushroom head at one of the four corners. More details are needed in order to show that the system is in any way responsible for the results of Mr. Eckles'

* *Engineering News*, March 27th, 1913.

Mr. Eddy.

test. The writer has not attempted to give an analysis for such a panel. It is customary to design wall panels differently from interior panels, but that is no argument against the approximate correctness of the analysis for interior panels.

To return from this digression to Mr. Godfrey's criticism that the results of the test slab were due to balancing loads on the over-hang: The tables and diagrams of the test show that in Loads 3, 4, 5, and 6—which were the ones particularly relied on for showing the behavior of the slab—the loading resting directly on the panel was more than twice as great as that on the entire surrounding over-hang, and, in the case of all the other loads, that on the panel itself was greatly in excess of that on the over-hang. These, consequently, were not balanced loads, and besides, there was no loading whatever on the areas above the column heads for Loads 1 to 6, inclusive, and no large loads later. The loads were applied over an area in the form of a Greek cross, with the intention that whatever load might be applied would be effective in causing bending moments and be situated so as to be less favorable to the mushroom slab than to its competitor.

The columns were 18 in. square and 5 ft. 6 in. from top of footing to bottom of slab, and not, as Mr. Godfrey asserts, "about half as thick as their height." Their diameters, as well as those of the mushroom heads, were in the usual relation to the span. This structure corresponded to a basement floor slab, but, because there were no upper floors, the columns necessarily had very small load stresses per square inch. That, however, did not affect the resistance the columns would afford to unbalanced moments, except to render the columns subject to actual tensile stresses in their reinforcing rods by reason of the small superimposed load. The columns were at a disadvantage for this reason and also because the unbalanced bending moment in the slab was not resisted by the stiffness of columns extending upward as well as downward from the slab, as would occur in a building. That may possibly be regarded as partly offset by the fact that the columns were only 5 ft. 6 in. long, but there was no such divergence between usual conditions and those of this test as Mr. Godfrey asserts.

Nevertheless, this test was not made (as seems to be assumed) to demonstrate the strength of this form of construction, *per se*, but to make a comparative test between it and another form of construction, and to demonstrate that though one operated on the principle of the beam the other did not.

The writer had nothing whatever to do with the design of the slab or the arrangement or carrying out of the test, except to suggest the Greek cross as the ground plan of the loading. The data obtained were submitted to him for discussion. Mr. Godfrey or any one else has the opportunity to discuss them and come to any conclusion the figures will support. Innumerable load tests of standard mushroom

slabs have been made. This test was not made to find out anything about the elastic behavior of mushroom slabs, about which there was any real doubt or lack of knowledge by those designing these structures, but to put the facts in evidence, and further to establish their manner of failure when stresses are carried beyond the yield point. This last was a most important piece of evidence which had not heretofore received such experimental certification as to settle it beyond dispute. Mr. Eddy.

It would seem on the face of it as if this test on a full-sized slab, in which all the details are carefully tabulated by reliable observers in such form as to admit of complete comparison with any other tests, might at least afford as good a foundation on which to base conclusions as the experiments made by Mr. Godfrey on a couple of glass plates under conditions not in accordance with those obtaining in floor slabs, and yet Mr. Godfrey intimates that absolute dependence is to be placed on the indications of his glass plates, and that the slab test should be disregarded as untrustworthy.

It may be that Mr. Godfrey believes that this test "has not even a theoretic interest", but he may find it difficult to persuade any to agree with him except those who are so wholly blinded by prejudice or interest as in fact to be unwilling that any reinforced concrete structures shall be built for use unless designed in such an innocuous manner as to be "out of the running."

Mr. Godfrey has also repeated his unsupported statements as to the unreliability of reinforced concrete construction under rolling or jarring loads, and seems to regard his mere assertion as sufficient to settle the question in this case also. In order to show how groundless is this opinion, which apparently has no other foundation than his own say so, the writer would quote from W. K. Hatt,* M. Am. Soc. C. E., as follows:

"It is well known that concrete, because of its lack of elasticity, absorbs or deadens vibrations, and the sound caused thereby. It is not probable that vibrations reach the steel. The speaker has knowledge of many experimental attempts to loosen the bond by shocks and vibrations. So far smooth bars encased in concrete that have been subjected to shocks and long-continued vibrations seem not to have lost any of their original strength of bond. Likewise the concrete on the compression side of a reinforced concrete beam that has been loaded and released from load some 2 500 times to high working stresses seems not to have been substantially weakened thereby."

For, far as these experiments go, they give no ground whatever for Mr. Godfrey's statement, into which he would seem to have been led by applying a line of reasoning derived from the behavior of all-steel structures which is inapplicable to reinforced concrete. An impact

* *Proceedings*, Nat. Assoc. of Cement Users, Vol. III, 1907, p. 60.

Mr. Eddy.

or blow at any point of a steel bridge is propagated longitudinally along elastic members extending linearly from the point, and it goes practically undiminished to the farther ends of those members, where it is subdivided among other members and propagated still farther. An allowance of 80 or 90% is usually added for impact to the static effect of a moving load.

Impact, or the effect of a blow at any point of a reinforced concrete slab, however, is entirely different from this. In the first place, the effect of the blow does not travel in one direction only, but in all directions radially from its point of application, so that in a very thin slab, its effect at any other point would be inversely as the distance, and in a very thick slab inversely as the square of the distance. This would make the allowance for impact in a slab very small.

Secondly, the effect of impact must be inversely proportional to the weight of the body receiving the blow. It may be assumed that steel costs from twenty to thirty times as much per ton as reinforced concrete, and the effect of impact on a steel structure costing the same as a slab would be from twenty to thirty times as much, for that reason.

Thirdly, the continuity and stiffness of the slab greatly reduce its vertical, lateral, and torsional deformations below those of a steel structure. The work done during impact, and its effect, depends on the amplitudes of the deformations. In particular, the horizontal resistance of a slab is many thousand times that of a steel structure. The vibratory energy absorbed by a slab during an impact is consequently small.

Fourthly, the small amount of energy which is absorbed is not transmitted (as it is in a highly elastic and resilient structure) to a considerable distance in the slab, but, owing to the nature of concrete, is dissipated near its source, transformed into heat, and rapidly absorbed.

Fifthly, slabs are tough, and not brittle, like terra cotta, for example, so that, in cases where great weights have fallen on them, little effect has been produced, whereas brittle slabs have been smashed under such circumstances, and have failed.

The concrete of the compression zone is such a shock-absorber as to protect the tension zone from jarring and vibration, both as regards steel in tension, and concrete as well.

For all these reasons the shock which a rolling load imparts to a slab is inconsiderable, and is absorbed and dissipated so readily that it is a negligible factor, instead of being such an important and overshadowing consideration (as Mr. Godfrey says) as to prevent its safe use in railroad viaducts and the like.

In support of these contentions the facts respecting the concrete railroad bridge, Fig. 21, which carries the track of the Soo Line between

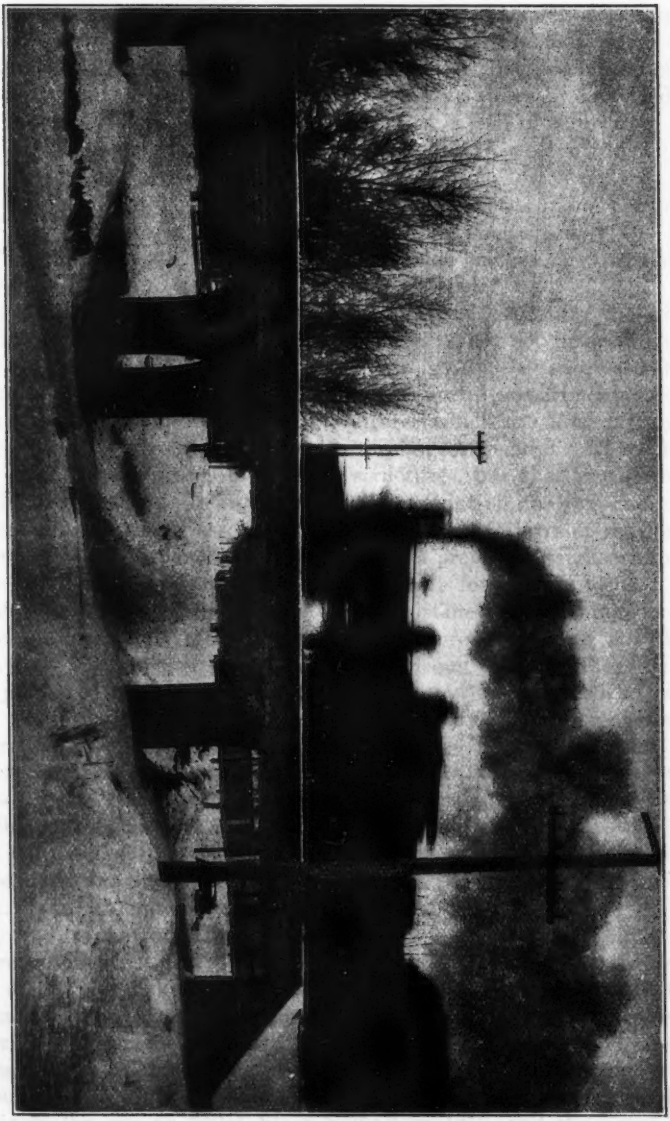

FIG. 21.—SOO LINE RAILROAD BRIDGE OVER WILSON STREET, AMHERST, WIS.

Chicago and Minneapolis over Wilson Street at Amherst, Wis., are instructive. It is a slab or girder, 18 ft. 6 in. wide and 2 ft. 3 in. thick, with reinforcement in excess of 1%, acting largely as a girder, but with some slab action, having a central span of 25 ft. 9 in. and designed to carry the heaviest locomotives with inappreciable deflections. It would be extremely difficult to cause failure by any loading that could be placed on it. It would require a load of more than 600 tons on this panel to cause a unit stress in the steel of 16 000 lb. This bridge has given such excellent satisfaction for years that the Superintendent of Bridges and Buildings of the Soo Line considers reinforced concrete as the desirable material for such spans. Mr. Eddy.

Particulars respecting other satisfactory slab bridges carrying street-railway traffic are to be found in the writer's book.*

It would seem that Mr. Godfrey's opinions respecting the availability of reinforced concrete for such purposes are not in accord with successful practice, and are not such as should be expressed with vehemence until they are supported by careful experimental tests, rather than by vague references to failures which are used merely to cast discredit on reinforced concrete design in general. There have been lamentable failures of all-steel structures, but that is no reason for discarding them. It is reason for discriminating analysis and careful design. The same lesson is to be derived from failures of reinforced concrete design, rather than to use them as a pretext for indiscriminate condemnation of reinforced concrete as unsafe for moving loads.

Mr. Eckles must have made some mistake in ascribing to the writer any previous attempts to treat reinforced concrete flat slabs. It is true that a paper on "Thin Homogeneous Circular Flat Plates" was published by the writer some years ago, but it contained no reference to any application of the flat slab theory. In the paucity of theoretical developments which could possibly furnish the basis for slab theory, this paper was used again and again in current engineering literature for that purpose, but the writer was in no way responsible for this, and in fact found so much in these applications with which he was at variance, for one reason or another, that he was induced to investigate the theory of reinforced flat slabs, as he has done in his book. The attempt now under consideration is his first effort in that line, and is entirely independent of his previous paper, and any reference to "his past efforts" simply reveals the lack of information of the one making such reference, and has no foundation in fact. When Mr. Eckles mentions discrepancies between the writer's former theories, and conclusions based on facts, it would be well to cite references, as the writer cannot recall any work of his to which these remarks apply. The only development of slab theory in any work of his is in the one on "Flat Floor Slabs," in 1913, and the paper now

* "The Theory of Flat Slabs," pp. 67-69.

Mr. Eddy.

under discussion is the application of the theory there developed to test results in several slabs. There is certainly no discrepancy here, such as Mr. Eckles would have us believe.

Mr. Thompson apparently does not understand the object the writer had in view in his paper. It was to show that test results as to deflections and stresses, as far as they were available, were in such accord with the analysis which he had proposed in his book that a reasonably close practical agreement existed between them, especially in the case of the mushroom system with which he was in a position to obtain inside information more complete than was the case with other systems. At the same time he utilized for comparison such information respecting other systems as was at his disposal.

Mr. Thompson seems to think that if he could show that the test slab of the Northwestern Glass Company's Building was insufficiently reinforced, or over-strained by the test load, or otherwise incorrectly designed, he would thereby discredit the computations in the paper; but such is not the case.

It is no doubt the truth, as Mr. Thompson alleges, that it is possible to draw further conclusions from the test data given than were drawn by the writer, and it may be surmised that the four conclusions stated by Mr. Thompson at the beginning of his discussion do not by any means exhaust the list. It is assumed that wall panels must necessarily differ in design from interior panels, and that every one conversant with slab design is perfectly aware of this, and hardly needs to have it called to his attention. It is believed that wall panels invariably differ in this way. The amount of that difference, however, is dependent to a large extent on the character of their connection with the walls and pilasters.

The deflections of Panel A shown in Fig. 7, when compared with those in Panel D, do not indicate that in this case the moment of resistance of Panel A as actually designed needed to be increased by more than a slight percentage to make its resistance equal to that of Panel D. As this is a question not yet entirely amenable to analysis, it remains to a very considerable extent to be determined in each case by the judgment of the designer. Other types of slabs having more flexible connection with the columns would no doubt require greater additional stiffness in wall panels than was needed in this case.

The principal questions at issue, however, as seen by Mr. Thompson, appear to be based on his two assertions that Equations (*a*) and (*b*) do not in fact give results that accord with tests, and as the principal support of that assertion, the further assertion that the observed stresses at gauge line 111 were not abnormal, but such as to be expected. The writer will proceed to meet these assertions at some length and then treat other matters broached by Mr. Thompson.

Mr. Eddy.

It should be stated first that the writer had nothing whatever to do with the design or testing of this slab, nor with that of any of the other slabs treated in this paper, and it is a subject of regret with him that the number of gauge lines over the column heads was so small, and that they were so irregularly distributed. However, he was compelled to make the best use possible of the data at his disposal, and he is still of the opinion that his interpretation of the results is substantially correct, as he will proceed to show by making use of analogous data from an unpublished test which has been put at his disposal since the paper was written.

Additional Data.—This is the case of a slab, 7 in. thick, with panels 18 ft. square, design load 150 lb. per sq. ft., and loaded at once over four panels forming a square, with a load which if uniformly distributed would have an intensity of 151 lb. per sq. ft., but disposed so as to leave several open spaces. It is estimated that the stresses in the steel over the center column were such as would be produced by a uniform load somewhat in excess of the design load. The four loaded panels were two wall panels and two adjacent interior panels, just as in the Glass Company test.

Fig. 22 is a plan of the central column head and the slab rods crossing it, with the outer ring rod 8 ft. in diameter, the inner ring rod 4 ft. 6 in. in diameter, and the cap 3 ft. 4 in. in diameter. The plan also shows the relative positions of the numerous 8-in. gauge lines, most of which were in the semi-circle most distant from the wall, and the length of the laps drawn to scale. Each belt consisted of thirteen ¾-in. round rods, except the direct belts which cross the wall panels from pilaster to column, and these had sixteen rods each.

The measured stresses, with the mean embedment of the axis of each rod at the extremities of the gauge lines, are given in Table 16.

Gauge lines 14 and 44, were on the top and bottom of the same rod, as were 15 and 42 also, from which it is evident that the other observed stresses on the tops of rods are most certainly in excess of the mean stresses to which the rods were subjected. Especially must this be true at the edge of the cap, where there is a sudden change in the flexibility of the slab. For that reason it is quite uncertain what actual mean stresses are indicated by the stresses which were observed on the upper surface of the rods crossing the edge of the cap radially; but we may be sure that they are much smaller than those corresponding to observed elongations.

It thus appears that some part at least of the excessive stresses apparently found here are due to placing the gauge lines on the upper surface of the rods, and the explanation which has been offered for these excessive stresses as being due to the thick boss formed by the head is needed as a reason to account for only a fraction of the observed results.

Mr. Eddy.

Equations (a) and (b), proposed for computing the maximum stresses in the slab rods of side and diagonal belts, respectively, in the head, give results which do not differ greatly from each other.

Let $W = 50\,000$ lb., $L = 216$ in.
$A = 13 \times 0.11 + = 1.4365$ sq. in.
$d_s = 5.5625$ in.

Then Equation (a) becomes

$$f_s = \frac{50\,000 \times 2 \times 216}{800 \times 5.56 \times 1.43}\left[\frac{3\,(216)^2}{(216 - 40)^2} - 1\right] = 12\,000 \text{ lb. per sq. in.};$$

but $L'^2 = 2\,(216)^2 - (96)^2 = 102\,528$, and $B' = 265.4$, and Equation (b) becomes

$$f_s = \frac{50\,000 \times 216 \times 3.37}{400 \times 5.56 \times 1.43} = 11\,500 \text{ lb. per sq. in.}$$

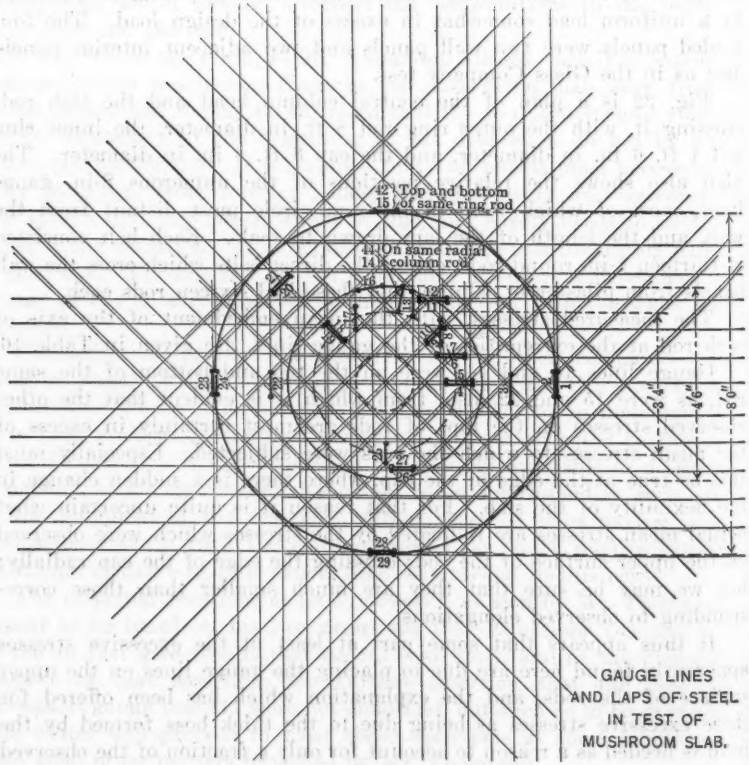

FIG. 22.

16	33	3 750

The reason that these computed values are in excess of those observed, lies in the quantity of steel to be found in the laps, as shown in the plan, which quantity is evidently largely in excess of that for which the formula was computed, as will be seen on referring to page 32 of "The Theory of Flat Slabs," where it appears that the mean cross-section of the slab steel was assumed to be 4.25 times the area of a single belt. The case in hand certainly exceeds this, as all the belts are lapped as far as beyond the inner ring rod, with a consequent reduction of the stress at the edge of the cap of perhaps 25% below the value computed by Equations (*a*) or (*b*).

It should be noted that the observed results show some diminution of stress with the embedment, but, in the slab rods themselves, this is

Mr. Eddy.

by no means proportionate at the edge of the cap to their approach to the neutral axis, although it is more closely proportionate elsewhere.

All these gauge lines were located around the central column corresponding to Column 45 of the Northwestern Glass Company Building. Besides these gauge lines, seventeen more were observed at three other column heads corresponding to Columns 36, 37, and 44 of Panel D, on the edge of the loaded area. The gauge lines, with one or two exceptions, were located (as were those around the central column) so that the edge of the cap nearly bisected each of them. The largest pair of stresses observed showed 7 400 and 7 700 lb. per sq. in., respectively, being on parallel adjacent diagonal laps. The next smaller observed stresses were 6 450 and 6 250 lb. per sq. in., respectively, with no other values as large as 6 000. In general, the values of the maximum stress in these gauge lines varied from 70 to 80% of those over the head of the central column. The two first mentioned appear to be abnormally large for some unknown reason as others similarly situated were much smaller.

Again, in Mr. Lord's report of the test of the Deere and Webber Building,* Fig. 14 shows cracks on the upper surface of the slab within an inch or so of the edge of the caps in the loaded area; but these cracks cannot be said to lie more outside than inside of the edges of the caps. It is clear, therefore, that those radial gauge lines that cross the edge of the cap in Fig. 22 will unquestionably show maximum steel stresses. Gauge lines 13, 14, and 44 give no indications that maximum stresses are to be found outside the cap. These additional data are thus seen to be confirmatory of the substantial accuracy and applicability of Equations (*a*) and (*b*).

Recalculation of Equations (a) and (b), in the Northwestern Glass Company Building.—Consider now the effect of the distribution of the actual loading. Suppose that Load 3, which consisted of 380 000 lb., were at first uniformly distributed over the four panels, each 16 by 17 ft. Next, let the loading on an area 7 by 8 ft. over the central column, and amounting to about 20 000 lb., be entirely removed and be piled on the surrounding parts of the slab. This will practically leave the cantilever portion of the slab around the column without loading, and will place this loading outside the inflection lines which surround this column. If similar removals occur at other columns, so that the loads are nearly symmetrically disposed on the central parts of the panels and the side belts, then it will be of little consequence, as far as the stresses in the cantilever portions of the slab are concerned, whether the loads outside the lines of inflection are uniformly distributed or have wide open ways across them; the stresses in the cantilevers will necessarily be increased by removal of the loading from the cantilevers to the other parts of the slab.

* *Proceedings*, Nat. Assoc. of Cement Users, Vol. VII, 1911.

Mr. Eddy.

Mr. Thompson says that the stresses "are more affected by the [total] amount of load in the panel than by their position". That certainly is not the fact, for, to take an extreme case, the loads might possibly be applied directly to the tops of the columns and produce no stress in the slab. The fact is that removal across the lines of inflection affects the stresses in the cantilevers, and removals within other portions of the panels affect the moments in those portions of the panels where the removals occur, but as long as they are symmetrical, such removals have little or no effect on the cantilevers.

In the paper it is in effect assumed that this removal added more than 10% to the effect of the load, as far as the stresses in the steel at the edge of the cap of the center column are concerned, and such allowance is believed to be not too great. Mr. Thompson disagrees with this on general reasoning, based apparently on principles applying to beams simply resting on supports, instead of firmly fixed to stiff supports, in which the position of the lines of inflection would be affected by the distribution of the load to an extent which is not the case in slabs, where the lines of inflection are practically fixed in position and remain the same for different distributions of load. Mr. Thompson, however, apparently states the truth inadvertently when he asserts that "the same load uniformly distributed would not have caused larger stresses than was caused by the load placed as shown in Fig. 5", for, as we have just seen, it would certainly have produced smaller stresses.

In case the lines of inflection are practically unaffected by shifting the load from the cantilever, as just described, the stresses at the edge of the cap will be increased, and it will also be justifiable to neglect the effect of any change in distribution of loads due to the center aisles, 18 in. wide, when treating the cantilevers, though perhaps not in treating other portions of the slab.

On repeating the calculation of the maximum stress at the edge of the cap, as given in the paper, the figures were found to be somewhat inaccurate by reason of using an incorrect value for the clear span between the caps. The correct figures are:

Diameter of cap $= 50$ in.; diameter of head $= 87$ in.

$L_1 = 204$ in., $L_2 = 192$ in., $B_1 = 204 - 50 = 154$ in.

$L'^2 = (204)^2 + (192)^2 + (50)^2 = 86\,049.$

$L^2 = (204)^2 + (192)^2 = (280)^2$. $B' = 280 - 50 = 230$ in.

If $W = 106\,250$, $d_3 = 6.5$ in., and $A_1 = 15 \times 11 + = 1.6567$ sq. in.

Then, by Equation (a), $f_s = 20\,700$;

and by Equation (b), $f_s = 19\,500$;

which values may need to be increased somewhat for lack of laps, as previously stated.

Therefore, a mean value of 20 000, say, must replace the erroneous value, 17 000, originally given.

Mr. Eddy.

It would be interesting to see the calculation by which Mr. Thompson says a value of $f_s = 15\,400$ is obtained by the application of Equation (*b*). The only change which he has suggested in the computation consists in scaling down the load of 106 250 lb. per panel, which he says is too large, though that does not appear to be the fact, as has already been shown. However, proceeding on that basis for the moment, let the load be scaled down to 96 000 lb. per panel, then, provided the originally computed value given in the paper ($f_s = 17\,000$ lb.) were correct, we should find $f_s = 15\,400$ lb. Recalculation, however, makes the value of f_s at least 19 500 instead of 17 000 lb., and the scaled value would consequently be 17 600 instead of 15 400, a discrepancy of 2 200 lb. per sq. in., or more than 14 per cent. It must be that Mr. Thompson did not actually compute this by the formula, but accepted without investigation the erroneous figure in the text.

There were, in fact, no laps whatever in the slab steel over Column 45, and the general formula, as discussed on page 32 of "The Theory of Flat Slabs," would need to be modified slightly for that reason, so that, in applying Equations (*a*) and (*b*) to this case, the reduction of the cross-section of the steel in the belts below the mean value assumed in establishing the formula would require a corresponding increase of the maximum stress at the utmost of, possibly, 20% above that computed from the tentative coefficients in Equations (*a*) and (*b*). Indeed, 10% in addition to the computed stress is sufficient to cover the abnormal unit stress of 22 000 lb. at gauge line 111.

It may truthfully be said, therefore, that there is good agreement of Equations (*a*) and (*b*) with stresses in this test, even if the actual stresses be assumed to be considerably in excess of any observed.

Abnormal Stresses at Gauge Line 111.—Mr. Thompson has misunderstood the facts stated in the paper respecting the stress at gauge line 111, as he has confused the elbow rods with the slab rods. The eight radial elbow rods, shown in Fig. 15 under the slab rods, are of 1⅛-in. round steel, and are of great stiffness compared with the slab rods. As stiffness is proportional to the fourth power of the diameter, one of these rods is more than 80 times as stiff as a slab rod. These are the rods that were forcibly pried and held in position in the slab until relieved by the application of the test load, when they acted with that load in inducing stresses in the slab rods which they were unable to produce while acting alone, being held by the shrinkage stresses of the concrete. Thus, after the slab had once suffered flexure by the application of a considerable load, and had had a chance to recover, the radial rods and slab rods would come back to a position of equilibrium and mutual adjustment different from the one they occupied before the application of the load. A renewed application of loading would then show elongations and stresses measured from this new position

of equilibrium corresponding to the loading. If concrete was a perfectly elastic material, however, such an action would not occur. If any such steel stresses were around the edge of the cap at Column 45, as Mr. Thompson states, they could not fail to show at such a gauge line as 107, which crosses the edge of the cap. The assertion that the stress at 111 was not abnormal because it increased and decreased with the load, is inconclusive, because that depends on how much decrease occurred on the removal of the load as compared with the previous increase. The fact is that the decrease of stress at 111 on the removal of the load was so small as to make it apparent that some such action was occurring as has been described. That this is the correct explanation of the observed abnormal stress at gauge line 111 seems to be established conclusively by the observed unit stress of 11 600 lb. remaining after the removal from Panel C of all but 7 000 lb. of the load of 47 100 lb., and an observed unit stress of 10 300 lb. still remaining a day later. This abnormal stress after the removal of the load, such as is not shown at any other gauge line, makes it clear that the stress at 111 was abnormal before the load was removed, and nullifies any reasoning that leaves that fact out of account. Mr. Eddy.

Location of Gauge Lines.—A misconception is likely to arise respecting the matter of stresses inside the cap and outside of it, though disregard of the fact that absolutely sudden changes of stress cannot occur at any point of a rod, because such changes must be more or less gradual from point to point. Owing to this fact, and to the fact that the edge of the cap is comparatively thin, large stresses are to be found for some small distance inside the geometrical outline of the cap, and are not confined to the area strictly outside of it. Indeed, some designers, in order to take account of this, have assumed the effective diameter of the cap as 2 or 3 in. less than its actual diameter. This question has its bearing on the location of the gauge lines with reference to the geometrical edge of the cap.

Again, the single abnormal result cited by Mr. Thompson, and shown in his gauge lines, *A* and *B*, does not accord at all with what is generally known respecting the distribution of stresses at the edge of the cap, and, until more specific information is available, it should be disregarded because a single measurement of this kind cannot be depended on, even were it not known that it is abnormal. It would be quite understandable that whichever of Mr. Thompson's gauge lines, *A* or *B*, lay across a crack would show the greater stress. As seen in the Deere and Webber test, however, that might as probably occur with *A* as with *B*; or it may merely be due to a so-called kink in the rod being straightened out, or merely the extra tension in the upper surface of the rod.

Mr. Thompson's attack on the validity and general accuracy of Equations (*a*) and (*b*) is thus seen to have a very slight foundation in

Mr. Eddy.

test data, and his estimate that the actual stresses may exceed those computed by these equations by as much as 45% may be disregarded.

Mr. Thompson says, respecting Mr. Turner's test slab, that it was broken by loads placed on the center panel, with comparatively little load on the projections. That is the truth, Mr. Godfrey and his balanced loads, to the contrary, notwithstanding. Mr. Thompson criticizes the test because it was not directed toward elucidating the particular problem in which he is interested. Mr. Turner, however, had in view the solution of a different problem, for which he was willing to expend money. Neither was that problem the one Mr. Godfrey would like to have seen investigated. It will be interesting and valuable for these gentlemen to investigate the problems they have in view, but they can hardly expect others to put aside their own pressing problems because they themselves are not interested in them.

It may be stated again, however, that, so far as can be learned from numerous load tests of mushroom slabs, central deflections of panels are unaffected by loading adjacent panels, which, if true, may permit this test to be used to solve some of the problems proposed by these critics. However, it is perfectly evident, from the report of the test and the photographs of the failure,* that Mr. Thompson is mistaken if he supposes that the steel and concrete just at the edge of the cap were ultimately more severely stressed than at points somewhat farther from the center of the columns, for the test slab gave way at points at least as far distant from the cap as gauge line 103, instead of at the edge of the cap, and this was a case of belts without laps.

Mr. Thompson entirely misses the point of the argument, respecting the comparison of the stresses at Column 36, and those at Column 46, which are similarly situated with respect to Load 3. At 36 the stress lines given are those largely due to the loads in Panel C, and at 46 to loads in Panel D. Whatever changes occurred at 46 by increasing the load on D might be expected to be paralleled, were the load on C increased. What is there "absolutely misleading" about this? From the behavior at 46 when the load on D was doubled, it might perhaps be surmised what would happen at 36 were the load doubled on C, which it was not. What misleading conclusion has been here advanced?

Certainly there is nothing so misleading in this as in Mr. Thompson's statement that the slab bar on which gauge line 103 was taken "was one of the outside ones of the diagonal band". In fact, however, the bar was the third one from the center bar and the outside ones were the seventh from the center bar, all equally spaced, and so this bar was not half way to the outer bar, where it was asserted to be by Mr. Thompson. That, unquestionably, is "absolutely misleading".

* "The Theory of Flat Slabs," p. 92.

Mr. Eddy.

Mr. Thompson criticizes the values obtained for stresses in the steel in the diagonal and rectangular bands because, he says they "are calculated from formulas derived without regard to the size of the column head, and, * * * would apply to a construction with a column head equal to a sharp point and one of any size whatever." He says "this assumption, on the face of it, is erroneous". Whether erroneous or not, one thing is certain, *viz.*, the stresses, if correctly computed on the assumption stated, will not become larger on account of making the head of appreciable size. The effect of the head, if anything, will be to decrease the calculated stresses at mid-span, and the error, if such it be, will be on the side of safety, and on that account is unobjectionable, from a practical standpoint, however much it may detract from the accuracy of the formulas. As the criticism is based on what appears "on the face of it", it might be well for Mr. Thompson to make an estimate, if he can do so, as to the amount of the effect produced at mid-span of these belts by ordinary sized heads, when due consideration is given to the fact of the comparative fixity of the lines of inflection, thereby conferring on the central parts of the panels outside the cantilever a semi-independent character, which justifies the assumption as one approximately correct. The final proof of the applicability of the formulas, however, is to be found in their accordance with test results, as has been shown in the discussion of the tests.

Mr. Thompson criticizes Equations (*a*) and (*b*) because the observed stresses at the edge of belts opposite column centers fall short of those computed from these equations. It must be remembered that these equations were derived on the supposition that the steel was as near the top of the slab as it is over the column caps. As it is in fact at a much lower level at the edges of the belts, less stresses will be observed here. This is part of the reason for the occurrence of large stresses at the edge of the cap; but the theoretical stresses thus computed furnish a basis on which to compute maximum stresses in slab steel over the head.

Mr. Thompson objects to the word "theoretical" in this connection. The word correctly designates a result reached from a consideration of the predominating principles involved. It does not mean, when applied to engineering structures, that all factors have been introduced into the premises. It means such simplified assumptions and premises as will take account of the dominating factors and give as a result a reasonable approximation which is accurate enough for practical purposes. As neither Mr. Thompson nor, so far as is known, any one else has proposed an approximate theory in any practical agreement with experiment, it would seem to be the courteous thing not to assail a proposed theory on the basis of assertions which seem not to be well founded.

Mr. Thompson says that a design, such as that of the Northwestern Glass Company Building, does not have a proper factor of safety, the

Mr. Eddy.

inference being that radical changes of design are required, whereas it appears from the preceding analysis and tests that all that is required to bring down the unit stresses in the steel at the edge of the cap, and reduce them by any desired amount, is merely to place additional short rods across the cap between the slab rods, of a length from three-tenths to four-tenths of the span, and no general alteration of design is required, as is intimated.

Mr. Thompson refers at the same time to stresses in the concrete. It is not the object of the paper to go into that subject further than absolutely necessary, and it will be postponed for future consideration, with the remark in passing that, where an absolutely flat slab is not required, every one is aware that increased thickness of slab in the vicinity of the cap will reduce the concrete stresses.

What the writer is especially concerned about in this discussion is, not the close accuracy of the particular computations of this paper (for they are admittedly based on average data which do not necessarily coincide altogether with the particular examples to which they are applied), but to convince those interested in slab construction of the fact that a method has been found for making a rational analysis of slab design, a method which will ultimately enable the engineer to predict results with somewhat the same certainty as is now attained in ordinary structural work. That may require modifications of constants, etc., in his practical formulas, which apply to the mushroom system. Such modifications will be no greater than every engineer uses in bridge construction where a method is used, which is not expected to result in the same final formulas for stresses in all types of bridges.

This paper proposed to discuss "Steel Stresses in Flat Slabs," and see how closely they could be computed by the analysis published by the writer in his book. Mr. Mensch regards the paper as taking up the general defence of the mushroom system. That is an unwarranted enlargement of the scope of the paper. He seems to think that if he can make it appear that any of his numerous objections to flat slabs are admissible, he has thereby cast discredit on the paper in some way. Let it then be said, by way of preface, that Mr. Mensch has not called attention to a single discrepancy between the computed and the observed results. The only discrepancies mentioned by him are between results given and confirmed both by analysis and experiment with what he believes they should be.

The real question at issue, however, is this: can the writer actually compute steel stresses in any one type of flat slabs correctly? We are led to believe that Mr. Mensch thinks he cannot do this, but instead of meeting the main issue directly he introduces a number of side issues. The side issue with which he begins and ends his remarks is the question of the factor of safety in flat slab construction, and the load tests he has made on his own constructions, showing a factor of safety of at

least 4. He also "claims that flat slabs designed according to Mr. Eddy's formula have only a factor of safety of 2, under the most favorable circumstances". Now, this is not so, because, in the case of the test of the St. Paul Bread Company Building, given in the paper, and designed according to the standards of the mushroom system for a load of 100 lb. per sq. ft., one panel was loaded with 415 lb. per sq. ft., without showing signs of distress or any cracks except a few very fine hair line cracks, to be discerned only with difficulty. That observed result would seem to have more weight than any mere estimates on which Mr. Mensch bases his claims, and would tend strongly to make us put no trust whatever in the claims which he has put forth so confidently. According to him, that slab ought to have failed under half the final test load. The truth of the matter is that the materials of which it is composed are used more economically and will carry more load than if disposed as Mr. Mensch proposes in a slab-girder construction, and though he is willing to concede a slight advantage to flat slab construction, weight for weight, his adoption of a wrong theory prevents him from giving flat slabs the credit to which they are entitled. Mr. Eddy.

Mr. Mensch declares that extensometer measurements of steel stresses afford no correct indication of the strength of a slab, and load tests, evidently, in his estimation, afford no reliable indication of what may be expected beyond the loads actually applied, as he believes a slab is subject to sudden collapse from sudden and unforeseen large stresses in the steel which may be expected to develop with slight increments of load; but, were this the case, this phenomenon should have been met frequently in the course of the numerous tests which have been made. So far from this being the case, the fact is that multiple reinforcement is of such a nature that unusual stresses developed accidentally in any rod of a slab must ultimately be distributed and divided among neighboring rods and thus be safely carried.

Mr. Mensch is mistaken in ascribing the discrepancies between observations at symmetrical points in slabs to sudden changes in stress under comparatively small increments of loading, such as have occurred in beams. A study of the stresses given in connection with the test of the St. Paul Bread Company Building, where these discrepancies were observed, fails entirely to reveal any such phenomenon as this. The discrepancies were in general as pronounced at smaller as at larger loads, with no such sudden increases of stress as alleged. This might well be expected in beams when cracks develop, but a crack such as ordinarily occurs in a slab would not have any such observable effect. It would be necessary for cracks to cross one another in the slab in a way such as they practically never do, to permit even the initiation of effects similar in character to those due to single cracks in a beam.

Almost at the beginning of his discussion Mr. Mensch turns from the discussion of slabs to that of beams, which he makes his principal

Mr. Eddy.

side issue. He says that "one may reasonably expect that the discrepancies will be still greater in flat slab construction", because the percentage of reinforcement is less than in beams. The entire purport and effect of the reasoning and the results reached in the paper go to establish the fact that slab action and beam action are different, theoretically and numerically, and it seems almost useless to attempt to reply to criticisms based on a complete confusion of beam action with slab action. Mr. Mensch says that slab action is "simply a combination of continuous beams acting in at least two directions, which beams are connected with each other and with the columns, and the deflection in any point is common to at least two beams acting at right angles to each other." By that statement he means to say that a theory of computation based on such an assumed network of beams combined together would constitute a sufficiently close approximation in its action to that of a flat slab to afford a practical basis for obtaining the stresses in a flat slab.

The writer does not hesitate to deny that there is any such agreement between the results of such a theory and any set of trustworthy experimental observations that Mr. Mensch can produce. Mr. Mensch refers in particular to Danusso as an exponent of this correct theory, and as one who expresses real slab action in a scientific way. Danusso's papers, to which he refers, have been translated into German and published in book form, so that they are perfectly accessible to any one.* As must be evident, such a network of beams necessarily has supporting girders at the edge of each panel, and the system corresponds to a slab-beam-girder construction or else to a slab-girder construction and not to a flat slab construction. Danusso, consequently, makes certain suppositions respecting the stiffness of these supporting girders, as is perfectly proper to do.

The writer has developed a slab-girder theory which is awaiting more complete experimental confirmation before publication, but any such theory must necessarily differ from flat slab theory and it is absurd on the face of it for any one to think that the results of either theory are applicable to another construction from that contemplated in deriving it. Flat slabs without supporting girders are alone under discussion in this paper, and Mr. Mensch's definition of slab action quoted above does not apply to actual flat slab action.

Mr. Mensch says that "the advocates of many flat slab systems declare that the common beam theory does not apply to flat slabs," and that he "has never seen a similar statement in the works of St. Venant, Winkler, Grashof, Föppl, or Müller-Breslau," and that, "in particular, the case of flat slabs was solved by Winkler and Grashof by that theory". Of course, St. Venant, Winkler, and Grashof made no

* "Kreutzweise Bewehrte Eisenbetonplatten," Danusso-von Bronneck, Berlin, 1913, Wilhelm Ernst und Sohn.

statement about flat slabs, for the very good reason that they had not been introduced in their day. Flat plates, however, is a different question. A flat plate is understood to be homogeneous and of the same moment of resistance throughout; a slab is neither of these, but has increased moment of resistance where required locally. St. Venant, the greatest investigator of the theory of elasticity that ever lived, was much busied with the theory of flat plates thick and thin. A full and critical account of his researches may be found in the encyclopedic "History of the Theory of Elasticity and Strength of Materials," by Todhunter and Pearson, occupying pages 833 to 896 of Vol. I, and pages 1 to 282 of Vol. II. He did not treat flat plates on the beam theory at all, but on the basis of the exact general theories of elasticity, without regard to the approximations involved in the beam theory. He was born in 1797 and died in 1886. Grashof, born in 1826, published the second edition of his great book on "Elasticity and Strength" in 1878. This is the edition to which Mr. Mensch has referred elsewhere and is the one always quoted. It contains his investigation of homogeneous flat plates, but nothing about slabs. Those who have not ready access to this work will find the substance of the more important parts of his plate theory in Lanza's "Mechanics." Mr. Eddy.

It is impossible to explain how a man of Mr. Mensch's careful scholarship could have been led to say that Grashof solved flat plates, not to say flat slabs, by the beam theory. Nothing could be farther from the truth. Grashof is regarded as the great exponent of the slab theory, if not the originator of it, as distinguished from beam theory. It is true that Mr. Mensch in a paper of his* has used Grashof's formulas, and may have supposed that they were established as beam formulas, but such is not the case. Müller-Breslau has not treated flat plates or slabs in any of his published works. It is useless to try to have any beam theory of flat slabs accepted on the authority of any of these writers.

Danusso, in his preface, quotes at first the formula of "Grashof's plate theory", as he calls it, and later the Bach-Föppl formula, which is a convenient modification of Grashof's. It thus appears that Föppl used the plate theory rather than the beam theory that Danusso uses.

It is entirely gratuitous for Mr. Mensch to charge up any defects in the Niagara Building, to which he refers, to others than those responsible for its design, and it may be that the writer will be as ready as any one to condemn its faults if such there be, when he is apprised of the details of the design, of which he is as yet ignorant.

Mr. Mensch criticizes the idea of saying that a set of loads extending across a slab would tend to produce a cylindrical trough or depression under it across the slab, and that another set of loads extending across the slab at right angles to the first set will also tend to produce

* *Proceedings*, Nat. Assoc. of Cement Users, 1911, p. 205.

Mr. Eddy.

a cylindrical hollow or trough across the slab under it, so that in the panel where these troughs cross each other the slab will be "dished" and their mutual effect will be for each trough to diminish the other. He declares that this description is "mysterious" and one that "will not enlighten any one", and yet this is the very idea of a cylindrical trough that Mr. Godfrey uses as the basis of his argument in his experiment. The idea is used by the writer merely as a semi-popular form of description, to assist the imagination in picturing this phenomenon, a phenomenon which he has investigated analytically from an entirely different point of view. It was used in order to put forth a form of explanation which would enable the reader to see how the results which had been reached by his analysis might possibly be pictured; and yet Mr. Mensch says this explanation is used because the writer does not care to express real slab action in a scientific way. It is evident that the critic has not followed the analysis, and is not even aware that that is exactly what has been done in the writer's book, where he has based his analysis on the general equations of equilibrium of the forces, shears, and moments acting on the external surface of an infinitesimal element of the slab, as is necessary in order to make a perfectly exact and rigorously scientific investigation of the slab.

It is evident that, with such divergent views of what constitutes slab action and slab theory, it would be useless for the writer to try to come to any understanding with Mr. Mensch within limits now at his disposal, especially when he insists, as he does, on the theoretical identity of flat slab construction with girder and slab construction.

In the interest of truth and fair play there is one correction that should be made in Table 15 given by Mr. Mensch. This table, which has been quoted several times in current literature, is based on one originally given by Mr. A. B. MacMillan, in which he computed the steel in the Turner slab for two different values of unit stress, *viz.:*

(*a*) at unit stress 16 000; weight = 549 lb. per panel;
(*b*) at unit stress 13 000; weight = 718 lb. per panel.

Mr. Turner explicitly stated that his formula, $\frac{W\,L}{50}$, was based on a unit stress of 13 000 lb., and Mr. MacMillan* made the same statement. The 718 lb. is consequently the only figure for which Mr. Turner would be responsible, and the weight of 549 lb. is entirely unauthorized, as his formula of $\frac{W\,L}{50}$ avowedly was based on a unit stress in the steel of 13 000 lb., as appears by reference to his book, page 29. For an assumed unit working stress of 16 000 lb., Mr. Turner's moment formula would become, in round numbers, $\frac{W\,L}{40}$.

* *Proceedings*, Nat. Assoc. Cement Users, Vol. VI, p. 266.

Mr. MacMillan further stated his ignorance respecting the amount of steel in the radial and ring rods of Turner's mushroom head, and assumed that their function was merely to support the slab rods in position at the top of the slab. The steel in the head would, in fact, be in the neighborhood of 200 lb., and it is evidently sufficient to add considerable stiffness over the columns, so that a conservative estimate of the steel per panel in Mr. Turner's construction would be 900 lb., instead of the figure wrongly stated by Mr. Mensch. This figure would be further increased by the usual laps over the column heads, so that substantial misrepresentation is made, intentional or not, by this garbled quotation. Mr. Mensch was himself present and contributed to the discussion of Mr. MacMillan's paper and has first-hand knowledge of these facts. It should be further noted that Mr. MacMillan's design, as shown by him in his paper, is almost identical with Mr. Turner's, with the omission of the inner ring rod, and his weight of steel only slightly exceeds Mr. Turner's design, as above corrected. Mr. Eddy.

He states* that:

"Floors designed by his method have been low in cost, have shown remarkable powers of resisting abuse, have stood tests of twice the live load over an entire bay, not only without signs of failure, but with such trivial deflection that one is led to believe that the constituent materials are far from being stressed inordinately."

Observe that this loading is not over one panel only but "over an entire bay," which disposes of Mr. Godfrey's contention that such loading would be fatal to this kind of structure.

It will be noticed that Mr. MacMillan's computation of the slab steel, according to Grashof's formula, provides nearly the same weight of steel as Mr. Turner uses, and would properly require additional steel to form a stiff head such as Messrs. Turner and MacMillan use. In round numbers, the weight of steel in either of these three slabs is, in all, 1 000 lb. per panel. These computations are really based on a flat plate theory of slab action in distinction from beam theory. The other four computed weights in the table are really based on beam theory, and require about twice as much steel, or about 2 000 lb. per panel. Beam theory practically neglects the co-action of the various belts, which co-action is considered and allowed for in slab theory. It affords a partial relief from the tensile stresses arising from the applied moments, a relief traceable to action of the bond shear of the embedment.

The statements that have frequently been made respecting the meaning of the results shown in this table seem to be misleading, as a correct interpretation of them is apparently to the effect that a beam arrangement, such as is involved for example in two-way rein-

* *Loc. cit.*, p. 266.

Mr. Eddy.

forcement, requires perhaps twice as much steel as a slab which can develop true plate action.

The advocates of beam theory insist that any flat plate action that may be developed is uncertain and unreliable, and that slabs, in order to be safe, must be designed by beam theory.

The advocates of flat plate theory insist that innumerable tests have shown that flat plate action affords a perfectly reliable and dependable form of resistance when the design is properly made. The evidence for this proposition is regarded by them as perfectly conclusive, and they find it difficult, to say the least, to endure with patience the intimations which are continually made that flat slab design is essentialy unsafe unless it fulfills the requirements of beam theory. It would be just as logical to insist that a dome constructed so as to resist circumferential tensions must be designed on arch theory alone, and neglect circumferential action in the dome, as to insist that a flat slab, with a multiple-way reinforcement tied together by the embedment, must neglect the effect of that embedment.

Mr. Hatt is ready freely to admit the facts of which all who have made tests on buildings are perfectly aware, namely, that the observed stresses in the steel are actually about one-half as great as would be found by considering the steel to resist the entire applied moments.

If other critics have known the facts and have not been willing to acknowledge them, they have been disingenuous; if they have not known them, they were disqualified to discuss the subject by their ignorance of the essential basis of the discussion. Either alternative would seem to discount the value of the opinions which such critics have expressed, and would seem to make the basis of their opinions dubious.

When Mr. Hatt, however, refers to the tensile stresses in the concrete, which he says carry the remaining fraction of the applied forces, he evidently has in mind direct tensile stresses in concrete, acting parallel to the steel and to be added to those in the steel, such as would disappear and be ineffective whenever cracks appeared across these lines of stress. That is a naïve and quite natural explanation, and one which is evidently correct in the case of reinforced concrete beams, but can be shown to be incorrect in the case of slabs.

Owing to the stresses which take place in multiple-way reinforcement in slabs, the shearing stresses due to the bond between reinforcement and concrete play a rôle, and have a fundamental importance, that has not hitherto been realized or understood, and they produce effects such as they do not produce in beams. This has been explained elsewhere. Concrete stresses arising from bond shear may be correctly designated as indirect stresses, in distinction from those previously

mentioned as directly due to bending. They are operative and to be depended on as long as the bond remains intact, which is until final failure, and long after the cracks due to the direct stresses of bending have appeared. These indirect stresses are the ones which produce the effects Mr. Hatt recognizes. His judgment tells him that direct tensile stresses are unreliable. Agreed; but should he become convinced, however, that the concrete in combination with the steel in the slab affords a resistance of a reliable kind, as it does not in beams, he would be in a position to revise his estimates as to a correct basis for safety of design. Mr. Eddy.

In tests up to perhaps one-half of the design load it is usual for direct stresses in concrete to be of so much assistance to the reinforcement as to make the steel stresses comparatively small. For larger loads, up to two or three times the design load, or more, direct stresses cannot be relied on, but indirect stresses are predominant in the concrete. The true properties of reinforced concrete, as a combination which is sufficiently fine-grained to exhibit resistance such as might properly be ascribed to a single homogeneous material different from either steel or concrete, then appear. It is to this that the formulas of the book on Flat Slabs apply, as they do not to lower stresses. The material is one that is tough and not subject to sudden collapse or unexpected failure, and will show perfectly evident signs of distress long before gradually giving way. Such material must not be made with its bars too large or too far apart, as that makes it too coarse-grained and decreases the surface on which bond shear acts.

Comparatively few tests to destruction have been made in slabs, but those that have been made fully support the view here advanced. When, however, the experimental evidence shall become sufficient, Mr. Hatt will feel compelled, doubtless, to accept it as a fact, but the same can hardly be said of a number of those who constantly discuss slab theory in print, but who are so wedded to preconceived *a priori* conceptions as to how slabs must act as to be wholly incapacitated for any change of view, no matter what the facts may be. For reasons stated at the beginning of the paper, the writer disagrees with Mr. Hatt's opinion that the controlling factor in slab design should be the compressive stresses in the concrete rather than the tensile stresses in the steel. One reason for this is the uncertainty still existing as to the resistance which concrete or any other solid can offer to hydraulic compression. For example, does any engineer suppose for an instant that the rocks in the depths of the earth's crust, which are subject to enormous hydraulic stresses by reason of the superincumbent strata, are thereby crushed or rendered less able to resist shear or tension?

Mr. Eddy.

The condition of the concrete under compression in a slab is not comparable to that in a test block or cylinder in a compression test, so that the uncertainties respecting the concrete in a slab are greater, if possible, than those respecting the steel, and the measured compressive stresses in the concrete, on which Mr. Hatt would rely, furnish no reliable criterion, for it is highly probable that shearing rather than compressive stresses are the determining factors in the ultimate resistance of the concrete.

ROAD CONSTRUCTION AND MAINTENANCE.

An Informal Discussion.*

By Messrs. William de H. Washington, Willis Whited,† William H. Connell,† P. E. Green,† A. F. Masury, and W. R. Farrington.†

ENGINEERING ORGANIZATIONS FOR HIGHWAY WORK.

Mr. Washington.

William de H. Washington, Assoc. M. Am. Soc. C. E.—In connection with the discussion of the subject of highway engineering organizations, the members of the Society are referred to a report to the Hon. John N. Carlisle, Commissioner of Highways of the State of New York, by the Board of Consulting Engineers consisting of Harold Parker and George C. Diehl, Members, Am. Soc. C. E., and the speaker. In addition to covering specifications for various types of roads and pavements and the materials to be used therein, the report considers the subject of efficient organization for the State Highway Department of New York, and gives in detail the work to be covered by such an organization, the duties of the various engineers included in the organization, and charts covering the interrelationship of its component parts. The report is on file in the Library of the Society.

Mr. Whited.

Willis Whited, M. Am. Soc. C. E. (by letter).—In reply to the very able and interesting discussion which has been elicited on this subject, the writer would call attention to the following points:

Mr. James includes Pennsylvania among the States in which road taxes are paid in labor. This was abolished by an Act of Assembly in 1911, and all road taxes are now paid in money.

Much is said on the subject of the construction and maintenance of improved roads, that is, roads covered with some kind of paving. More than 90% of the roads in the United States are not improved, in

* Continued from March, 1914, *Proceedings*.
† Closing discussions.

Mr. Whited.

the sense mentioned, and probably will not be for many years to come. The most important problem that confronts the State highway administration, is to make these roads as good as possible at a minimum expense, and generally with a view to more permanent improvement at some future time. If an engineer has work to do that is worth $10 000, and has $10 000 with which to do it, the proposition is comparatively simple, but if he has $10 000 worth of work with only $1 000 with which to do it, a very high grade of engineering ability is called for.

Engineering is a union of common sense and science. It deals with the forces of Nature; but by far the most difficult force with which the engineer has to deal is human nature, and ability to deal with human nature can hardly be acquired in any college course. It requires genius, to begin with, and proper training, which includes a good knowledge of the fundamental principles, including moral principles, and the ability to apply them effectively.

Mr. Durham's remarks bring out strongly the fact that although the organization in Paris is almost ideal, the results are open to criticism; whereas, in London, notwithstanding the fact that the organization contains obvious defects, the results are excellent; and in Berlin where everything is under the control of a Government which has a genius for organization, the results are variable. These facts point strongly to the indication that administration is a personal matter, rather than a question of form of organization, and, to produce the desired result, it must be sufficiently elastic to permit of all men being assigned to the duties for which they are best adapted.

The French are very systematic and competent, technically, but inferior to the English in executive ability. The Germans are very skillful and industrious, but are so accustomed to military rule that difficulty is apt to develop in case of an emergency requiring special methods.

The writer is often inclined to deplore the position of many in the Profession who advocate the placing of engineers at the head of all work that is even partly of an engineering nature. The combination of a high grade of technical skill and knowledge with the sure and accurate judgment of men that is required in any high administrative position, together with the proper understanding of the many legal, commercial, and political questions involved in State highway administration, is so rare as hardly to be looked for on this earth; and, for a man at the head of such an organization to be notably deficient in any of the latter requirements is almost certain to wreck the department; whereas, a man possessed of these qualifications, as well as the self-control and tact required for such a position, can usually make a success of it, even though he is equipped with but a moderate amount of technical knowledge. A man possessed of the latter, with a sufficiently elastic

Mr. Whited.

organization, will have the power and the disposition to avail himself of any special knowledge or skill possessed by any member of his staff, whatever his title may be, in the solution of any problem that may present itself. Every man has his weaknesses and deficiencies, and it is of the utmost importance that the "Chief" see that none of them is allowed to interfere with the smooth running of the organization.

The writer would suggest that the most important qualifications of the head of any department of public works are tact, common sense, self-control, and the ability to deal with men, both personally and commercially, and a knowledge of his legal rights and duties, as well as those of the traveling public, the public service corporations, and the abutting property owners. The more knowledge of engineering technology he has the better, but the questions which arise in strictly administrative work are generally questions which must be settled on the spot, while those of a technical nature can usually be referred to some expert in paving, bridge construction, tests of materials, etc., who should be included in the staff of the department.

A word as to the politician: The general idea is that the politician is a professional criminal, whereas, the fact is that politicians of the higher grade are fully as honest as men in most other lines of business, and are not only possessed of tact and common sense, with a thorough knowledge of the world, but are also industrious as a rule.

As to the statement by Mr. Bennett, to the effect that a prominent engineer has said that there were few engineering problems to be faced in highway work, the writer would say that a good definition of an engineer is, a man who can do with one dollar, what any one can do with two; but, considering the many millions of dollars spent annually on road construction and maintenance, and the importance of the interests involved, there is ample scope for the exercise of the best grade of engineering ability.

It is doubtful whether anybody has reached, or ever will reach, a final settlement of the conflict between the inspector and the contractor's foreman, at least in the present state of human nature. The strictly competent inspector does not exist, and never will, and the same may be said of every one connected with the work. The only thing to do is to fight out each individual question as it arises. The writer will suggest, however, that a frequent cause of the differences between the contractor's foreman and the inspector of small and limited experience, is that the foreman, or some of his workmen, with or without the knowledge of his superiors, will in some way get the better of the inspector when he is off his guard, and the inspector finds it out when it is too late. The anger, suspicion, and hostility which takes possession of the inspector need not be explained to any one understanding human nature. It is easy to deceive anybody, but it is almost certain that it will be found out eventually.

Mr. Whited. Regarding efficiency boards, the writer would say that the efficiency expert has his place in all public or private work, but his outgivings can seldom be taken as final, because so much depends on the personality of the officials and employees, both high and low.

Mr. Connell. WILLIAM H. CONNELL, ASSOC. M. AM. SOC. C. E. (by letter).—The discussions on "Municipal Highway Engineering Organizations" would seem to indicate that there is a general tendency to raise the standard of organizations controlling this important branch of engineering work. The exceptions taken to the organization advocated by the writer are matters of minor detail, and in some cases are due to a misunderstanding. A few of those who discuss the subject are apparently under the impression that the writer advocated a standard highway organization. This, of course, is not the case, as such an organization would not be possible on account of the varying sizes of the municipalities; but an attempt was made to outline the general principles which could be followed in forming an organization suitable for municipalities of various sizes. Some seem to dwell at length on coping with existing conditions. That, of course, is necessary, but is simply routine; it would not do, under any conditions, to plan an ideal organization which could not be operated successfully under different laws, ordinances, and existing conditions, over which no control could be exercised; and, therefore, the first thing to do is to plan the work in such a way that it can be carried on successfully and economically under existing conditions, and try to have these conditions improved so that the ideal organization can be put into operation in the course of time.

One of the questions of detail, on which there seems to be some difference of opinion, is whether there should be a separate organization for maintenance. It would seem to be logical that the organization to take charge of the maintenance should be the one under which the pavements were constructed, as the men in that department understand all the conditions in connection with that work—some of which might at a later date be factors in the maintenance problem. Having a single organization also does away with the shifting of responsibility. The maintenance is just as important a part of the road problem as the construction, and no pavement should be laid without taking into consideration, among other things, its probable life and the probable maintenance charges during its life.

Another very important consideration, in having one organization in charge of both branches of the work, is that it tends to build up a better personnel and makes the men more generally useful. In other words, an important part of the education of the highway engineer is to understand and realize the importance of the maintenance problem. A good many of them do not realize the importance of this problem

Mr. Connell.

because, in many cases, separate divisions are in charge of the construction and maintenance, and the men who have nothing to do with maintenance, as a rule, devote very little time and study to the subject. There is no doubt that more study would be given to the general highway problem if all the work was under one organization; the engineers who constructed the pavements would know that they were to be held responsible for the maintenance, and would naturally give more time and thought to this phase of the work. Aside from this fact, it would require a smaller organization if combined than if separate, as each division—no matter how well organized—tends to a duplication of work, to a certain degree.

One member advocates the general scheme of organization, but points out that the weak point of the system is in the question of personnel, and further states that in the United States there is no trained class of public works officials or Government engineers, organized like the French corps for bridges and highways. In view of this, he states that, in the light of possible conditions, it would seem to be better policy to concentrate along all classes of work, organizing the bureau in sections for doing specific things, in charge of the man best qualified to do them. This, of course, is a proposed scheme to cope with existing conditions, which is just what should be avoided. Engineers are often too apt to accept conditions as they are, instead of trying to improve them, and if they do not strive to form an organization that will stand and that is not dependent on any one man suited to fill a particular position, the organization can never be a stable one. A highway organization should not be dependent on any individual, but should be designed so that it would be constantly training men to fill the vacancies of those passing out, and it would appear to be better policy to endeavor to change the conditions that prevent formulating an organization of this kind, than to become reconciled to existing conditions.

A very important consideration in connection with the highway organization is the question of the *esprit de corps*. Mr. Meeker states that the key-note of all successful organizations is that all must work harmoniously. No matter how well the corps is organized, without harmony it will be a failure. This is a very important matter, and cannot be given too much attention as a factor in the control of a good working organization for this or work of any other class.

There was some discussion regarding the method of handling the patrol inspection. The writer advocated that the street-cleaning force should be combined with the general highway organization, and that the maintenance patrol inspection of the pavements should be handled by the street-cleaning inspectors or the foremen. The advisability of this method was questioned. This was advocated in order to increase

Mr. Connell.

the usefulness of the men in charge of the inspection work, and thus reduce the cost of the patrol inspection by utilizing men already on the work, such as the street-cleaning inspection force, instead of employing additional men to cover the ground every day. There is no reason why the police could not also be utilized for work of this kind, and when our municipalities are further advanced, and more on a business basis, there is no doubt that they will be more generally used in connection with matters of this kind than at the present day.

If some general principles were formulated relative, not only to the character of the organization, but the details of conducting the work, resulting from discussions of this kind, they would carry a certain weight and would be a great help to engineers throughout the country in having the laws, regulations, and ordinances changed to make it possible to plan an organization in accordance with what is conceded to be the best practice by the authorities on this subject. In other words, it is always easier to put into effect anything that is the combined opinion of the engineers of the country at large than it is to accomplish it by individual effort.

FACTORS LIMITING THE SELECTION OF MATERIALS AND OF METHODS IN HIGHWAY CONSTRUCTION.

Mr. Washington.

WILLIAM DE H. WASHINGTON, ASSOC. M. AM. SOC. C. E.—Based on experience as a contractor and engineer, the speaker wishes to emphasize the importance which he attaches to traffic censuses in connection with this topic. In this matter, much may be learned from European engineers, as traffic censuses have been taken for many years in both France and England. Such censuses, and soil and geological surveys, should form an important part of the work preliminary to the design of any highway.

During its investigations in New York State, Commissioner Carlisle's Board of Consulting Engineers,* realizing the variety of local conditions obtaining in different parts of the State, recommended a "material" survey of the State, in order to make available to the Highway Department information of inestimable value if local materials were to be used economically.

As an example of proper utilization of local material might be cited the case of a section of Route 4, extending across the southern tier of counties of New York. It was found that an appropriation of $1 000 000 was available for the construction of more than 150 miles of road. In order to meet the demands of the people for a maximum amount of mileage to be constructed under this appropriation, the engineers had designed a single-course semi-Telford road. The local material available was a soft sandstone which would rapidly disin-

* Report of the Board of Consulting Engineers, 1913.

tegrate under wear and weather. Due to long hauls from railroad stations, it was found that the importation of limestone for the base and trap rock for the top would require the expenditure of a large sum of money. The Board of Consulting Engineers, therefore, decided to construct a cement concrete top, using for the mineral aggregate the local sandstone, on a base of sandstone, and to complete the pavement with a bituminous carpet. Mr. Washington.

Highway engineers require more definite knowledge relative to the life of various types of roads when subjected to varying local conditions. Massachusetts, apparently, is about the only State which has made a careful series of records covering the wearing qualities of certain classes of materials and types of roads under given traffic conditions. Every State should emulate Massachusetts and endeavor to ascertain, under their local conditions, the value of the materials which are available for road building and the service which a given type of road will give under known traffic, and careful records should be taken covering the rate of wear under traffic and the deterioration due to various climatic conditions.

Mr. Crosby has mentioned the subject of harmonic action and harmonic waves in road surfaces. This expression was evolved by that able engineer and road builder, Col. R. E. Crompton, of London, who has ascertained that roads have a tendency to creep or to form miniature hills and hollows. With certain types of traffic, he has found that the distances between the hills and hollows have a certain relative length. The speaker, in company with Col. Crompton, examined one road on which there were more than 1 000 motor busses per day, and found a series of long waves, which occurred with great regularity throughout the length of the road. The speaker believes that improper rolling of the road and the compression of the material are the main factors influencing the formation of harmonic waves. Traffic further develops the harmonic waves due primarily to the vibration of the motor cars passing over them. During the process of rolling it will be noticed that the material rises in front of the front roller and pushes ahead to a certain extent, finally ceasing to move forward, at which time the roller goes over it. If examined, the road surface will be found to have a marked swell. Col. Crompton has endeavored to solve this problem by devising a machine with three sets of rollers, instead of the ordinary tandem roller. The first and third rollers are somewhat lighter than the second one. The first roller consequently smooths and compresses the material, but does not put excessive weight on it. The second and third rollers give the additional compression necessary. It has been found possible to secure a much smoother base and surface for the road with this triple roller than with the ordinary tandem roller.

Mr. Green.

P. E. GREEN, M. AM. SOC. C. E. (by letter).—It is gratifying to find such a general agreement as to the main points among the eminent engineers who have engaged in this discussion. Naturally, there have been some sharp disagreements, but these have been rather few. Apparently, road construction and maintenance are becoming standardized, a result to be desired in many ways.

Mr. Whinery seems to object mildly to the suggestion that the esthetic features of the highway should be considered, but it is believed that his objections are not well taken. It is so easy to consider them, the result is so desirable—often at little or no additional expense—that it would appear poor policy, both from a utilitarian and artistic point of view, to ignore such benefits. Too often engineers are justly charged with lack of appreciation of that very point.

It is believed also that Mr. Whinery is incorrect in his statement that the temporary and inadequate railways built in the early days resulted from the undeveloped conditions of the principles and requirements involved, rather than from financial or economic considerations. Undoubtedly, much poor engineering was perpetuated, but also much of it was of the highest order, in that it adapted its construction to its pocketbook. It is comparatively simple to build well with an unlimited pocketbook, but certainly a higher order of intelligence is often required to do well with little money.

As to the roadway diagram, Fig. 1, it would appear as if Mr. Whinery failed to use it with the discretion advocated by the writer. According to the diagram, the roadway width of the boulevard having 600 vehicles per foot of width should have been at least 80 ft., instead of 38 ft., as it actually is, and, if future traffic increase is taken into account (as it should be), the width would be increased accordingly. It cannot be maintained that the roadway width is a straight-line function of the traffic. It is believed Mr. Whinery would think better of the diagram in question if he studied it and its text a little more carefully.

Mr. Tillson encountered the same obstacle that the writer found; that is, the difficulty in describing "new matter", but he got around it more gracefully. However, the writer disclaims its authorship; it was simply one of the Society's rules governing this discussion.

Mr. Tillson further calls attention to the late practice of the City of Paris in treating paving blocks with oil under pressure to the amount of 10 or 12 lb. per cu. ft. This is largely for the purpose of preventing the blocks from swelling. The writer, however, believes that swelling will not be prevented in that manner. At Longview, Tex., in September, 1913, after a hot dry summer, it was found that blocks treated with true creosote oil in 1911 absorbed nearly 50% of their volume of water and had lost nearly 50% of the contained oil.*

**Engineering News*, December 4th, 1913.

It is believed that there is only one way to treat wood blocks permanently so that they will not absorb a great deal of water, and that is by traffic. Mr. Green.

The writer thoroughly agrees with Mr. Meeker and Mr. Washington that the so-called "harmonic" waves are caused more by poor workmanship and materials than anything else. On Diversey Boulevard, Chicago, paved with bituminous concrete in 1911, at a section having a mixed traffic of about 5 000 vehicles per day, evenly divided as to direction, one side has pushed into these waves so that it has become exceedingly rough. The other side is quite smooth. This condition is apparent for only about 2 000 ft. The rest of the highway (several miles) is in perfect condition. It is very evident that defective material or workmanship or both has been the cause of this.

EQUIPMENT AND METHODS FOR MAINTAINING BITUMINOUS SURFACES AND BITUMINOUS PAVEMENTS.

Mr. Washington.

WILLIAM DE H. WASHINGTON, ASSOC. M. AM. SOC. C. E.—Three members of this Society were engaged by the Highway Department of the State of New York to devise methods of maintaining highways and reducing the cost of maintenance. They concluded that the railroads had set a very excellent example as to the organization for upkeep, by which they put this work in the hands of a body of men under a competent foreman, instead of distributing their men individually over a section. These men work as a unit. Each group of men is provided with all necessary materials, which materials are usually carried on hand cars.

The speaker has devised a machine to accomplish exactly the same object in connection with the maintenance of roads, and meets the requirements mentioned in Mr. Farrington's paper. This movable repair plant consists of a motor truck equipped with all tools and machines necessary for the maintenance of highways, and supplied with storage capacity for broken stone, sand, and tar. The machines include a pressure spraying device, sand and stone chip distributor, a roller (beneath the body of the truck), a stone and sand dryer, a mixing machine, a road sweeper, a revolving power scarifier, extension arms for pulling a plow, scraper, split-log drag, or a snow plow, a power loader and derrick, and all requisite small tools. The truck has storage capacity for about 4 tons of broken stone and from 12 to 14 bbl. of tar. When used for the repair of macadam roads, a large removable water tank is carried on the truck.

The outfit has been designed with the intention of utilizing it in the maintenance of all types of roads and pavements constructed by the State Highway Department of New York.

Mr. Masury.

A. F. MASURY, ESQ. (by letter).—There is no equipment better adapted for the maintenance of bituminous surfaces and bituminous pavements, or for making roads, than motor trucks; and probably none is more generally in use for this purpose.

This discussion will give facts, based on the actual operation and maintenance of trucks, which will enable the engineer and contractor to operate them to the best advantage in road work.

Factors of Motor Truck Operation.—Glaring generalities have been characteristic of most discussions on motor truck operation. The motor truck salesman, with his optimistic figures and his aggressiveness to make a sale, has caused the engineer, contractor, and merchant to use his figures in planning truck operation. This, done without much thought on the part of the owner, really gives him the salesman's figures of past performances on which to base his intended operation.

The commercial motor vehicles are machines, made in a variety of types and sizes, designed for specific purposes, and must be built, their field of operation laid out, their operation controlled, and the upkeep looked after, by engineers.

The purpose of this paper is to present data on different sizes and types of motor trucks, to show actual figures as to their performance, and state the factors which must be used in operating them.

Arrangement of Space for Most Economical Storage.—In storing motor trucks, it has been worked out in practice that they can be handled best in a building of usual size by arranging them in two rows with an open aisle between; that is, the trucks are backed into place, with their fronts facing the aisle. This permits them to be taken out without any delay, and also allows them to be run into the aisle, where washing and drainage facilities should be provided.

In most buildings, posts are necessary, and should be toward the front of the trucks, but far enough back to allow the trucks to turn out into the aisle. The depth from the wall to the post should be at least 16 ft. 6 in.; thus, the front wheels of trucks of most sizes will project beyond the posts and allow an easy and quick turning into the aisle. The aisle should be about 27 ft. wide in order to provide a practical turning radius for getting out or backing in. The posts should be about 22 ft. apart, so as to allow the storage of three large trucks between them. Where a large number are stored the proportioning of small to large trucks allows this arrangement to be worked out with the economical use of all space.

The size of the doors should be looked into very carefully, as trucks, especially of the van type, are now very large. In order to take those of the largest type, such as vans and those used for crackers

and paper boxes, the doors should have a clearance of at least 12 ft. 3 in., and should be double, opening outward. The clearance between the butts of the doors should be at least 10 ft. 9 in. This allows sufficient space for the fastenings of the doors, without interfering with the trucks as they move in and out. There should be lights on the butts of the doors on each side, quite high up. Mr. Masury.

The elevators must also be considered carefully. They must be at least 24 ft. long and 11 ft. wide, in order to take the modern motor truck, and should have a carrying capacity of at least 7 tons, in order to accommodate the trucks when light. A heavier elevator, to take care of loaded trucks, is impractical, from a commercial standpoint; loaded trucks are not usually garaged in such buildings, but might be accommodated on the ground floor. The elevator should have four guiding rails, and a speed of about 60 ft. per min.

Service.—There must be adequate facilities for filling the tanks with gasoline, and oil, and for the storage of the large quantities of lubricants used in the operation of such trucks.

To comply with fire prevention regulations, the gasoline must be stored underground, and must be piped to at least two outlets on each garage floor. There are two practical ways of raising it to each floor: by hydraulic power and by pressure. Either of these systems can also be used for cylinder oil and kerosene. There should be at least one outlet for kerosene and one for oil on each floor. Meters should be attached to all outlets, and provision should be made for locking them. At least one portable tank should be provided for each floor, as trucks must be filled during the hours when the garage is most crowded, and when, at best, only two can be filled from each outlet.

Oil and kerosene may be carried to the trucks from the outlets in measures, as comparatively small quantities are used.

Transmission oil, cup grease, wood alcohol (for use in the radiators in cold weather), and other material and accessories may be stored in a room on the floor with the trucks.

There should be an efficient system for keeping account of the exact quantities of supplies consumed by each machine.

A dirty truck (and trucks collect dirt with astonishing rapidity) is much harder to keep in good order than a clean one, as dirt not only gets between moving parts and into bearings and causes wear, but it prevents the discovery of minor troubles until they have become major ones, and makes repairs a difficult and distasteful job if they are discovered. Therefore, trucks should be washed at night. For this purpose a regular force should be employed, its size depending on the number of cars to be washed. Four washers and two polishers can take care of fifty cars.

Mr. Masury.

Drivers are not always to be depended on to make repairs; their hours are long, and they have little time for them during the day's run. For this reason, if six or more trucks are being operated, it will be well to have a night repair man on duty, with one or two helpers. As the trucks come in, each driver should report any trouble with his machine. The repair man can also examine the trucks to discover loose bolts, and can grease them up.

Truck Sizes.—Trucks may be divided into three classes, according to the arrangement of the motor and the driver's seat:

Type 1.—This is the usual touring car type; the motor is over the front axle, the driver and control are behind the motor.

Type 2.—In this type the motor is over the axle; the driver and control are directly above the motor.

Type 3.—The motor is over the front axle; the driver and control are on one side of the motor, and the helper is on the other side.

Types 2 and 3 conserve the length of the chassis, as less space is taken for the driver and control, thus allowing a longer loading platform in proportion to the wheel base than Type 1.

The most important average dimensions for each size of truck are given in Table 2; and the diameters of turning circles are given in Table 4.

TABLE 2.—MOST IMPORTANT AVERAGE DIMENSIONS OF TRUCKS.

Type.	Capacity.	Wheel base.	Extreme length.	Length, back of cab.	Extreme width, in inches.	Height of Loading Platform, in Inches.		Clearance, in inches.
						Empty.	Loaded.

Factors in Cost of Operation of Motor Trucks.—Table 3 shows the cost of operation of trucks of standard capacities running at different mileages per day, and the factors in detail of each item of upkeep. These figures are taken from actual costs of operating trucks, and are nominal in every way. Interest is reckoned at 5% on half the cost of the truck; insurance at 2% on 80% of the cost; and amortization at 10 per cent. Mr. Masury.

Column letter in Table 3.		Formulas.
A	Capacity.	
B	Average cost of chassis, based on list prices of the number of manufacturers indicated by the figures in parentheses.	
D	Miles per hour.	
F	Driver's salary, per year.	
G	Cost of garaging, per month.	
H	Miles per day.	
I	Maintenance (small repairs, etc.), per year.	
J	Gasoline, per year.	
K	Oil and grease, per year.	
L	Tires, per year.	
M	Interest, per life.	$M = R\frac{B}{2} \times 5$ per cent.
N	Insurance, per life.	$N = R \times (80\%$ of $B) \times 2$ per cent.
O	Depreciation, per life.	$O = \frac{B}{10\% \text{ of } R}$.
P	Cost, per year.	$P = F + 12G + I + J + K + L + \frac{M}{R} + \frac{N}{R} + \left(O = \frac{B}{10}\right)$.
Q	Miles of life at each mileage per day truck is assumed to run.	
R	Years of life.	$R = \frac{Q}{W}$.
S	Cost, per life.	$S = P \times R$.
T	Cost, per day.	$T = \frac{P}{300}$.
U	Cost of tires, per mile.	$U = \frac{L}{W}$.
V	Cost of gasoline, per mile.	$V = \frac{J}{W}$.
W	Miles per year.	$W = H \times 300$.

Mr. Masury.

In Table 3 the cost of the body is left out intentionally, as it usually represents the amount of discount given by the manufacturer, and it needs but few repairs.

Tire Data.—The data on tire equipment in Table 5 show the average of the requirements and guaranties of the different tire man-

Mr. Masury.

ufacturers, and also the average cost of tires to the consumer. Column 2, the axle load, gives the average weight on the front and rear axle of trucks of each size. Column 3, the size of tire, shows the sizes usually recommended by tire manufacturers for the respective loads carried on each axle. Column 4, $\frac{L}{W \times C}$, means the load on the axle, in pounds, divided by the width of the tire (the width being taken at the place where the tire meets the ground); C is the circumference of the wheel. The figures in this column are pounds.

This factor takes into account the size of the wheel, and therefore reconciles the fact that a larger wheel can have a tire of a smaller size, and is a better factor to use in comparing tire sizes than the weight, in pounds per square inch, of tire in contact with road.

Column 5 shows the normal speed of trucks of each capacity. Column 6 shows the guaranteed mileage by the tire manufacturers. Column 7 shows the average price at which tires can be bought by the consumer.

Mr. Farrington.

W. R. FARRINGTON, M. AM. SOC. C. E. (by letter).—The writer notes that considerable attention has been given by those taking part in the discussion on "Methods and Equipment for Maintaining Bituminous Surfaces and Bituminous Pavements" to the use of motor equipment.

Not much has been done, as yet, with trucks in State highway maintenance work in Massachusetts. Trucks have been used in some cases, but, except for transporting broken stone, gravel, bituminous materials, etc., over long hauls, apparently have not demonstrated their economy under existing conditions. The writer has no doubt, however, that, as this work increases and longer sections come under maintenance, motor trucks with the necessary equipment for patching, etc., will prove economical and will come into general use.

As to the material truck described by Mr. Washington, though the writer has no doubt that this will be useful, there would seem to be some objection to its general adoption at present, as it is probable that many of the culverts and bridges, even on main lines, are not strong enough to carry a truck of this weight, and there is also some question as to the effect on the road surfaces.

Recognizing the injurious effect of very heavy trucks on roads, where the surfaces and foundations, as well as culverts and bridges, are not especially designed for such traffic, the Massachusetts Legislature in 1913 passed a law prohibiting the use on the highways of trucks weighing more than 14 tons, without a permit from the State, city, or town officials having charge of repairs on the highways, and it would not seem to be good policy for the State to use on its work trucks of greater weight than the public generally is allowed to use.

MEASUREMENT OF THE FLOW OF STREAMS BY APPROVED FORMS OF WEIRS WITH NEW FORMULAS AND DIAGRAMS.

Discussion.*

By Richard R. Lyman, Assoc. M. Am. Soc. C. E.†

Mr. Lyman.

Richard R. Lyman, Assoc. M. Am. Soc. C. E. (by letter).—Further thought and study, and the matter presented in the discussions on this paper, have confirmed the writer's conviction that the weir without end contractions is the weir which, in actual practice, will measure water in the most satisfactory way. When it is used, the diagrams‡ and tables presented in this paper give results, without computation, in accurate accord with existing experimental data. They give results, too, for a great variety of weirs, covering a wide range of heads, without that "troublesome correction" for velocity of approach.

Table Giving Discharges for all Weirs Without End Contractions, Within the Limits of Experimental Data.—For some purposes, tables giving discharges are more convenient than diagrams, therefore, discharges for a series of definite heads are presented in Table 69. Discharges for heads between those given may be found by interpolation.

Table Based on Formulas, Giving Discharges for High Heads.—A table of discharges, for heads higher than those for which accurate experimental data exist, by Gardner S. Williams, M. Am. Soc. C. E., has been published.§ The results are identical with those found by the use of Plate LXXXII. Therefore, no table for these discharges is presented in this paper.

* Continued from April, 1914, *Proceedings*.

† Author's closure.

‡ Blueprints (on cloth) of the original diagrams, and of diagrams more closely ruled, are made for field use.

§ "American Civil Engineers' Pocket Book", pp. 867-868.

Mr. Lyman.

TABLE 69.—DISCHARGES OVER SHARP-CRESTED WEIRS OF VARIOUS HEIGHTS WITHOUT END CONTRACTIONS.

These Figures were Taken from Plate LXXX, and are Therefore Based on the Experiments Made by Bazin, Francis, Fteley and Stearns, and Also on Those Made in the Hydraulic Laboratories of Cornell University and the University of Utah. The Limits Included in the Diagram and the Table are Fully Covered by the Original Experiments.

Table Giving Discharges for Weirs with Broad Crests.—Discharges over broad-crested weirs are given in Table 70. The matter it contains was prepared from Plate LXXXIII.

Suggestive Details for Weirs Recommended.—Suggestive details to be used in constructing weirs without end contractions are presented in Figs. 50, 51, and 52. It is recommended that the angle iron proposed for the crest have its end securely embedded in the walls of the channel; also that flush-gates, as shown in Figs. 50 and 51, be constructed so that the bottoms of the openings they cover will be on a level with the top of the floor of the channel of approach. If these flush-gates are of thin material, they can perhaps be located on the up-stream side of the bulkhead so that they will not affect materially the accuracy of the measurements. If supplied with lugs or iron loops, they may be pulled up and pushed down at pleasure.

Flush-Gates for Small Weirs.—For smaller weirs, the writer has used flush-gates of 1-in. lumber, with sheets of rubber gasket attached to them in such a way that they form a sort of flap or "check-valve". The pressure of the water on only one side of the gasket makes it fit close against the bottom of the channel and also around the three

Mr. Lyman.

sides of the opening. A hole is cut in the rubber, and the edges of the material around this hole are fastened to the down-stream side of the gate so as to make a water-tight joint. The greater pressure thus brought to bear on the up-stream side of the gate brings it snugly against its seat, thus making it possible for the gasket to resist the water pressure.

Quantity of Water Each Weir Will Measure, and Quantity of Concrete Required to Construct Each Weir.—Suggestive dimensions of weirs to be used for measuring definite quantities of water and also the number of yards of concrete required to build these structures are given in Table 71.

The horizontal notch shown just below the crest of the weir and extending down stream to the end of the wall is constructed to allow the air free access to the under side of the falling sheet. Conditions are often such that a hole may be made through the wall of the channel just down stream from and below the crest of the weir, as at *A*, Fig. 51. This feature must not be overlooked when accurate measurements are desired.

Comparison of Results Given by the Diagrams and those Computed by the Francis Formula.—Mr. Moritz presents two ingenious and very convenient diagrams for finding the discharge over two weirs by the Francis formula. The scale of his diagram for suppressed weirs, however, is small. In order, therefore, to compare its results with those given by the diagrams presented in this paper, the quantities used have been computed by the Francis formula. The results of this comparison are given in Table 72.

The figures above the heavy line are the results obtained under the conditions specified by Mr. Francis himself, *viz.*, that with a "depth of channel leading to the weir * * * as small as three times that on the weir" the Francis formula "agrees with experiment within less than one per cent.", therefore "if the canal leading to the weir has a suitable depth, it will be requisite only when great precision is required * * * to go through the troublesome calculation of correcting the depth on the weir".*

Table 72 shows that, even when the conditions specified by Mr. Francis himself are satisfied (conditions which all experienced engineers attempt to follow), differences occur, varying from 1.3 to 7.0 per cent. Plate LXXXI shows the degree of accuracy with which the diagrams and tables herein presented fit the great mass of experimental data shown on Plates LXXXVI*a* and LXXXVI*b*. It should be noted, however, that the Francis data shown on Fig. 8, Plate LXXXVI*a*, on which the Francis formula is based, are but an exceedingly small fraction of the accepted data. If it be argued that these diagrams do not give results which are absolutely correct, it cannot be denied

* "Lowell Hydraulic Experiments", pp. 134 and 135.

Mr. Lyman.

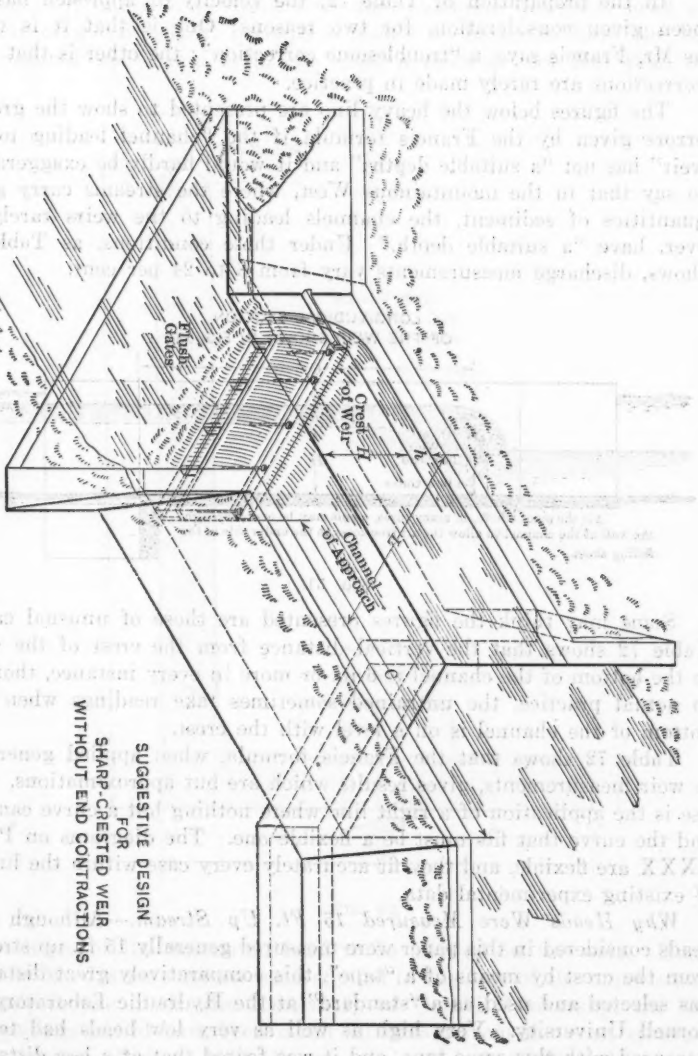

FIG. 50.

SUGGESTIVE DESIGN FOR SHARP-CRESTED WEIR WITHOUT END CONTRACTIONS

Mr. Lyman.

that these results indicate positively that one right line or formula of the Francis form, namely, $Q = mh^n$ cannot be made to fit accurately these actual experimental results.

In the preparation of Table 72, the velocity of approach has not been given consideration, for two reasons: One is that it is truly, as Mr. Francis says, a "troublesome correction"; the other is that such corrections are rarely made in practice.

The figures below the heavy line are presented to show the greater errors given by the Francis formula if the "channel leading to the weir" has not "a suitable depth;" and it would hardly be exaggerating to say that in the mountainous West, where the streams carry great quantities of sediment, the channels leading to the weirs rarely, if ever, have "a suitable depth." Under these conditions, as Table 72 shows, discharge measurements vary from 8 to 24 per cent.

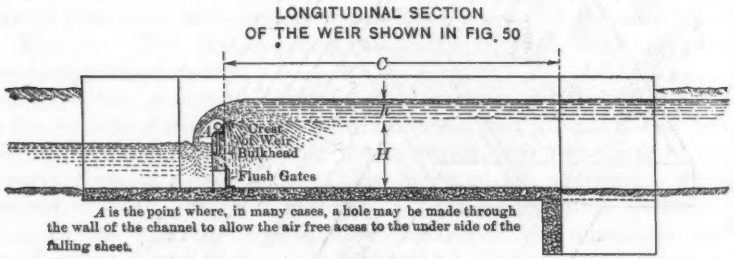

FIG. 51.

Some may think the figures presented are those of unusual cases. Table 72 shows that the vertical distance from the crest of the weir to the bottom of the channel is 6 in. or more in every instance, though, in actual practice, the untrained sometimes take readings when the bottom of the channel is on a level with the crest.

Table 72 shows that the Francis formula, when applied generally to weir measurements, gives results which are but approximations. Its use is the application of a right line where nothing but a curve can fit, and the curve that fits must be a flexible one. The diagrams on Plate LXXX are flexible, and they fit accurately every case within the limits of existing experimental data.

Why Heads Were Measured 15 Ft. Up Stream.—Although the heads considered in this paper were measured generally 15 ft. up stream from the crest by means of a "tape", this comparatively great distance was selected and used as a "standard" at the Hydraulic Laboratory of Cornell University. Very high as well as very low heads had to be measured with this same tape, and it was feared that at a less distance the "curved surface over the crest" might affect the readings for high heads. The cross-section of the channel of approach was so great, and

the floor in it so nearly horizontal, that the results thus obtained are perhaps the same as if readings had been taken as Mr. Hazen suggests, at a distance up stream "equal to 2.5 times the height of the weir." However, unless some limit fixes the maximum allowable head on a weir of given height, perhaps it would be better to have the heads measured up stream from the crest a distance not less than some

Mr. Lyman.

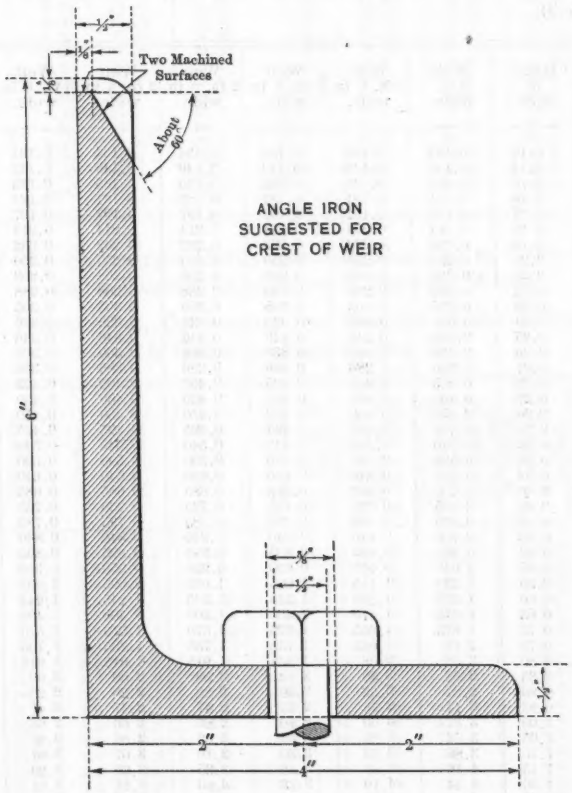

FIG. 52.

multiple of the maximum head to be allowed on the weir. Had the rule Mr. Hazen suggests been applied in the case of the upper standard weir in the Hydraulic Laboratory of Cornell University, the "tape" readings would have been taken up stream from the crest of the weir a distance of about 28 ft., because the weir is 11.25 ft. high.

Weirs Having Dimensions Proportional.—Concerning one other of the many excellent matters presented in the discussion of Mr. Hazen,

Mr. Lyman.

TABLE 70.—DISCHARGE, IN CUBIC FEET PER SECOND PER FOOT OF LENGTH, OVER BROAD-CRESTED WEIRS WITHOUT END CONTRACTIONS.

These Quantities Were Read from Plate LXXXIII, Which Is Based on Experiments Made on Weirs 11.25 Ft. High in the Hydraulic Laboratory of Cornell University. For the Discharge over Weirs of Heights Other than 11.25 Ft., Apply the Coefficients Given in Table 0.

Head, in inches.	Head, in feet.	Weir 6 in. wide.	Weir 1 ft. 0 in. wide.	Weir 1 ft. 6 in. wide.	Weir 2 ft. 0 in. wide.	Weir 2 ft. 6 in. wide.	Weir 3 ft. 0 in. wide.	Weir 3 ft. 6 in. wide.

Mr. Lyman.

viz., "that weirs which, in all respects, are proportional to each other will have the same coefficients", the writer wishes to say that for years he has attempted to get into clear form this same idea. Now that this principle has been clearly stated, he will attempt to demonstrate in the Hydraulic Laboratory of the University of Utah whether or not it is correct.

TABLE 72.—PERCENTAGE OF DIFFERENCE BETWEEN QUANTITIES OF DISCHARGE OVER WEIRS OF VARIOUS HEIGHTS, AS GIVEN BY PLATE LXXX, AND AS COMPUTED BY THE FRANCIS FORMULA: $Q_F = 3.33\,H^{\frac{3}{2}}$.

Q_F = Discharge, in cubic feet per second.

H = Height of weir, in feet.

The quantities above the heavy line are within the limits for the formula specified by Mr. Francis.

Head, in feet.	Q_F	Quantity, as Read from Plate LXXX.							
		$H = 0.5$ ft.	$H = 0.75$ ft.	$H = 1.0$ ft.	$H = 1.5$ ft.	$H = 2.0$ ft.	$H = 3.0$ ft.	$H = 4.0$ ft.	$H = 6.0$ ft.

The Weir Without End Contractions Gives the Most Accurate Results.—Mr. Moritz says the statement that the "sharp-crested weir without end contractions" gives "the most accurate results with the smallest amount of work * * * is open to serious question", as the use of such weirs "would be practically impossible on account of the large quantity of silt carried at certain seasons of the year" in the canals of some irrigation projects.

Mr. Lyman.

Great Velocity of Approach and Little Sediment Deposited.—The first of the six reasons why these weirs are best, given near the beginning of this paper, was that, with this structure, the velocity of the water above the weir is greatest, and therefore its capacity for carrying silt over the crest is also greatest. The second of the six reasons is that, with this weir, the channel of approach must be made of concrete, lumber, or some other material, that will retain a definite rectangular form; it is easy, therefore, to determine whether or not the channel is clean, and it must be clean to give good results. Another reason may now be added: This weir is best because its crest may be fixed in position permanently, and flush-gates may be built under it. Through these gates silt may pass when measurements are not actually being taken. Thus is maintained a relatively great velocity in this comparatively small channel of approach, and the channel is kept clean.

The Diagrams and Tables Fit Great Variety of Weirs and Great Variation of Heads.—Again, as previously explained, the diagrams and tables submitted in this paper (Plate LXXX and Table 69) fit, and fit accurately, a great variety of weirs of this type, and do so for a comparatively large range of heads. The Francis diagram or formula for suppressed weirs, based on only 17 experiments, cannot be expected to fit, nor does it fit, the great variety of weirs and the large range of heads to which it has been and is being applied. The smallest head used by Mr. Francis was greater than 0.73 ft., and the largest less than 1.1 ft.; his experiments, therefore, cover a difference in head of but little more than 3 in. Moreover, all his experiments were made on only one weir with only one height.

Francis Formula Fits Within Very Narrow Limits.—The Francis experiments are shown on Fig. 8, Plate LXXXVI*a*. The results obtained by other experiments are presented on both sides of this figure. They indicate that if Francis had used higher and lower heads, he would have discovered that no one equation of the form he uses ($Q = mh^n$) can fit accurately a series of experiments on weirs of the type herein considered.

The Best Practical Measuring Device Available.—Mr. Moritz closes his argument in favor of the Cippoletti weir with these words:

"In the writer's opinion, there is no better practical device, at present available, than the Cippoletti weir for measuring the quantities encountered in the majority of irrigation laterals."

The velocity of the water approaching the Cippoletti weir is less than that of the water approaching the weir without end contractions. In order to give accurate results, the cross-section of the channel of approach for the former must be greater than that for the latter. The deposit of silt, therefore, will be greater above the Cippoletti weir than above the weir without end contractions. If, then, with the Cippoletti

Mr. Lyman.

weir, as he explains, "one or two good cleanings of the pool during the season will generally suffice", less cleaning will be required for the weir without end contractions. Still more important is the fact that a conscientious water master may clean his canal so as to make a large pool, and a water master of the other sort may make but a small pool, or none at all. Table 72 shows what effect a change in the cross-section of the "pool" or channel of approach has on the discharge. In the case of the suppressed weir, the channel to be cleaned has a fixed cross-section, of concrete, timber, or other material, that will retain its definite rectangular section. With sluice-gates through the bulkhead under the crest of the weir, this channel can be cleaned with the aid of the water much more easily than can the "pool" of which Mr. Moritz speaks.

If the channel above the suppressed weir has 6 in. of silt in it, the discharge (by taking this fact into account) can be found from the diagrams and tables herewith submitted. This cannot be done with the Cippoletti weir.

The writer does not see wherein the use of the tables and diagrams recommended in this paper requires any greater care than does the use of the Cippoletti weir and the diagram Mr. Moritz submits. Neither does he concede that the Cippoletti weir is the simpler of the two, in the sense of its being easier to use; but he will concede that it may be installed at a little less cost.

Mr. Moritz does not give a reference to the experiments which he states show that the Cippoletti weir gives results "within an error of from 2 to 4% when the head is not greater than one-third of the crest length." However, as the Francis formula is used for computing the discharge over the Cippoletti weir, it is important to specify the distance of each contraction from the sides and from the bottom of the channel. Of course, the greater the cross-section of the channel of approach, the more nearly will conditions approach the ideal; and the nearer this ideal is approached, the greater will be the tendency to fill the channel with silt.

Accuracy of Results.—Mr. Moritz claims that the Cippoletti weir, under what he intimates are rather limited conditions, gives results "within an error of from 2 to 4%"; but he fails to give the quantity or value of the data on which he bases this assertion. He does explain, however, that "the quantities in these experiments were measured volumetrically", and intimates in the same sentence that there are errors in the tables and diagrams herein presented "due to the use of a calibrated measuring device * * * such as the 'standard weir' used in the Cornell Experiments," giving results which may be "accepted as accurate to within 2 or 3 per cent."

Evidently, Mr. Moritz has gone carefully over the matter presented in this paper, but he did not see for the moment that the "2 or 3 per

cent." applies to "Broad-Crested Weirs" (page 1523*), and not to "Sharp-Crested Weirs Without End Contractions" (page 1516*). It is for the latter weirs and for the diagrams and tables which accompany them that this paper makes its greatest claim. The results are based on the twenty "classic" series of experiments named on the left of Plate LXXXI. This plate indicates clearly with what degree of accuracy the diagrams and tables of this paper fit this unparalleled array of hydraulic data.† Mr. Lyman.

Discrepancies in Quantities for Weirs with Broad Crests.—To furnish the "additional light" for which Mr. Moritz asks concerning certain runs on broad-crested weirs, Fig. 53 has been made. The curves shown are drawn to fit the points based on the original experiments. These points are represented by large dots. The results reached by Mr. Williams‡ are shown by small crosses, and those obtained by Mr. Horton§ are represented by small dots within triangles.

The accuracy with which the results given by the diagrams on Plates LXXXV and XC fit those obtained by using the original data is shown by the circles on Fig. 53. This information and the original data on which Messrs. Williams and Horton also based their results are given in Table 73. From the quantities given, and their signs, in the column marked "Percentage of difference", it is seen that the results obtained by using Plates LXXXV and XC fit the original experiments almost perfectly. There are only five individual experiments which show a difference greater than 2%, and two of these would show still smaller differences but for the fact that slight errors in calculation were made in the original computations.

Accuracy with Which Diagrams Fit Original Data.—Attention is again drawn to Plates LXXXIX and XCI*a*. These plates show that the diagrams giving mean values furnish results which can be used with greater confidence than can the results of the individual runs. Other plates in this paper give the same information concerning the accuracy of the other diagrams.

Although the Suppressed Weir Is Recommended as the Best Weir, Other Measuring Devices Are Necessary.—It was not, as Mr. Johnston seems to have understood, the writer's intention that the weir be adopted by legislation as the only device for measuring water. The intention was to advocate that, by legislation, the weir without end contractions be adopted as the "standard weir". It can be used to obtain accurate results wherever any other type of weir can be used, and in many places and under many conditions where reliance can be placed on no other weir. If, as Mr. Robinson says, this type of weir

Mr. Lyman.

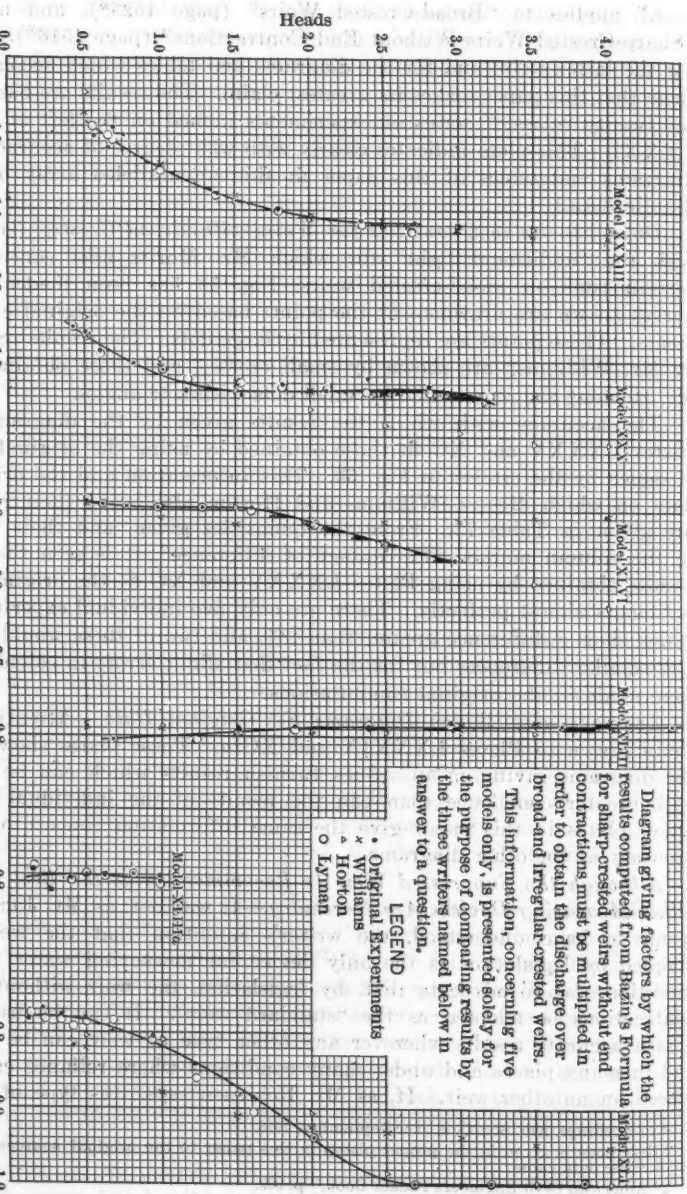

Diagram giving factors by which the results computed from Bazin's Formula Model XLII for sharp-crested weirs without end contractions must be multiplied in order to obtain the discharge over broad-and irregular-crested weirs.

This information, concerning five models only, is presented solely for the purpose of comparing results by the three writers named below in answer to a question.

Fig. 53.

were made standard by Federal Statute, then it would soon be used universally. By further actual experiment on this one weir, if the results based on the data at present available are not absolutely correct, data will be obtained from which more and more accurate results can be found. Mr. Lyman.

With this suggested standard weir, it is believed, gravel and silt can be disposed of, as already explained, without constructing the weir in a channel parallel to the main canal, as Mr. Johnston suggests.

Basic Theory on Which Diagrams Are Drawn.—As it was the intention to give the results of this investigation first and the theory afterward, it is not surprising that Mr. Johnston, in his discussion, states that the basic theory of the method used is not explained. He also says, after stating that the differences used cannot be shown with sufficient accuracy, when the rectangular axes are used, "it would seem to one who has not given extended study to the problem that Mr. Lyman continues to use rectangular axes."

On all the plates intended for giving discharges, it may be seen that the lines representing heads and those representing discharges are not at right angles to one another.

The beginning of the explanation of the graphic method used in the construction of these diagrams is on page 1534, headed "E.—Method of Determining the Proposed Formulas." Unfortunately, on page 1545 a reference to "Fig. 2, Plate LXXXVI*a* (right hand end)" should be to "Fig. A, Plate LXXXVI*b* (right hand end)". Further explanation of the theory on which the construction of these diagrams is based, and particularly that portion relating to the inclination of the axes is given beginning on page 1566 in the part entitled "I.—Method of Constructing the Final Diagrams."

Although Mr. Johnston's "basic theory" is certainly ingenious, and of intense interest from the mathematical point of view, it could perhaps not be applied so easily to the construction of the diagrams herein given as can the method, largely graphical, which was actually used in their construction.

The Results Fit Perfectly the Conditions Prevailing in Ordinary Irrigation Streams.—Mr. Winsor states, with respect to the experiments made on weirs without end contractions:

"Most of the observations thus far have been conducted under conditions quite foreign to those which are met in the operation of a canal system. The early experimenters used, in the main, larger streams than the ordinary irrigation stream requiring measurements, and the recent experiments were conducted under laboratory conditions which are seldom applicable to the ordinary irrigation stream."

The heads presented in this paper were measured with a "tape", or else have been reduced to equivalent "tape readings"; heads can be thus conveniently measured in any canal. Mr. Winsor did not suggest a simpler or more practical method. If the water in the canal system

is measured with any degree of care, then, with the heads measured as above, the conditions under which these experiments were made appear to be identical with those "met in the operation of a canal system."

We may wait long for many series of experiments to be made with such care that they will deserve a place among those used in this paper. It will certainly be a much longer time before future experiments will warrant disregarding these, even if the results they give are not "absolutely correct."

As to the quantity of water actually measured: Plate LXXXI gives the list of the experiments on which Plate LXXX is based. For the results given by Plate LXXX, some of which are presented in Table 69, a high degree of accuracy is claimed. These experimental data cover the limits given both on Plate LXXX and in Table 69. The

Mr. Lyman.

writer is confident that they will give accurate results under conditions "which are met in the operation of a canal system."

Little Additional Cost Brings Better and More Accurate Results.—The small additional cost of "constructing a channel of approach", instead of making "the enlargement of the up-stream portion of the stream bed to a sufficient area" (and Mr. Winsor might well have added to a sufficient depth), will, in the opinion of the writer, be much more than compensated by the additional convenience, accuracy, and satisfaction that will result. Mr. Winsor certainly appreciates the value of maintaining a large velocity of approach in this mountainous country, as does every other engineer who has had experience where streams carry great quantities of silt.

Information Concerning One Particular Weir More Needed Now Than Information Concerning a General Solution.—It is not clear why Mr. King thinks that, in order to be of general application, the solution to the weir problem "must provide for a channel of approach of any cross-section." Of course, conditions will arise which make it desirable to know what quantity of water with a given head is passing over some irregular crest having uncertain contractions. Great care has been taken and much space used to provide, in this paper, a means of measuring the quantity of water flowing over irregular weirs, and the results reached are satisfactory; but, when water is to be measured with a high degree of accuracy, the device to be used must be built for this purpose.

As the suppressed weir can be used under practically all conditions where accurate results are demanded, the writer thinks it better for hydraulicians, who are in a position to do so, to gather more information concerning the discharge over this weir than to attempt to get a "satisfactory general method of solution for all weir problems." Although this general information would be of interest and value, the writer regards the more scientific data as having a greater value.

The Greater the Velocity of Approach the Better.—As water rarely if ever flows over a weir without some velocity of approach, Mr. King's suggestion to secure data for this condition does not appeal to the writer as of great importance. In fact, as the greater the velocity of approach the more ideal is the weir for use where silt is carried in the water, would it not be better to gather information concerning weirs with smaller heights and therefore with still greater velocities of approach?

The Best Standard Weir for All Cases.—Taking into account the quantity and reliability of the data available, the range of heights covered by the series of weir experiments used herein (see list on Plate LXXXI), and the comparatively wide range of heads covered by these experiments, the writer must differ with Mr. Horton, and say that there is a weir "which is the best standard for all cases", and that it

Mr. Lyman.

should be so considered by all engineers until data are furnished that will show some other weir at least equal, in its general application, to that without end contractions.

Simplicity of Method.—Mr. Horton's discussion argues in favor of making "the computation as simple as possible by using the $\frac{3}{2}$ power of the head, instead of causing the head to vary according to some other fractional or decimal power, which would require the use of logarithms, logarithmic paper, or a logarithmic slide-rule for practical computations," and he closes remarking "regretfully, as regards hydraulic science, 'Of the making of many formulas there is no end' ".

Although this paper presents a great array of formulas, these are used, and are intended only to be used, for the purpose of preparing diagrams similar to those shown on Plate LXXX and in Table 69, from which, without calculation, discharges are obtained.

Mr. Smith states that he cannot agree that the diagrams herein presented are "in the interests of simplicity." Then he adds "errors in taking results from the diagrams can easily exceed the discrepancy between the author's and the Francis formulas." The writer believes that Mr. Smith will change his view after examining Table 72. If he takes the results obtained from Plate LXXX and checks them by Table 69, he will probably be surprised at the smallness of the "discrepancy."

Discharge Proportional to Length of Crest.—Mr. Smith says, again, "one assumption made at the outset of the paper is perhaps open to question. It is that the discharge is proportional to the length of crest."

In reply, attention is drawn to the fact that the famous hydraulician, Bazin, made very careful experiments on his two standard weirs, one having a length of 1 m., the other having a length of 2 m. Concerning the results obtained, he writes:

"All needful precautions were taken to insure a flow under exactly the same conditions as over the 2-m. weir. The height of the weir remained the same. It might, however, be asked whether, in view of a somewhat different distribution of the velocities, or of an increase in the effect of friction against the side-walls, the results would be strictly comparable. We have failed to observe any appreciable difference between the two series."

In the new canals of the Hydraulic Laboratory of the University of Utah, the writer hopes to be able to determine whether or not the discharge is proportional to the length of crest, and also if the friction on the side-walls, where the velocity is comparatively small, is a factor that must be taken into account when a high degree of accuracy is desired.

Mr Lyman.

Mr. Smith asserts, with others, that "the Cippoletti weir discharge is proportional to the length." If this were true in the sense that the same quantity of water passes over each and every unit of length of crest of this weir, it could be used for a dividing device, as can the weir without end contractions. A moment's reflection shows that water flows through the triangular areas outside of the ends of the crest proper; it follows, therefore, that the discharge is not proportional to the length. For this reason the Cippoletti weir cannot be used as an accurate dividing device.

Simplicity of Table 69.—The table of discharges (Table 69) is believed to be quite as simple as the table referred to by Mr. Smith, which he says "is so simple that an engineer is not required to interpret it."

Height of Crest of Cippoletti Weir Omitted.—If the "height" of the crest of the Cippoletti weir above the bottom of the channel of approach is not specified, then the statement made by Mr. Smith that the error, under the three conditions he names, "will be less than 1%" is far from correct.

One Type of Weir Should Be Established by Legislation.—"Exception," Mr. Smith says, "should be taken" to the "proposition to establish one type of weir for universal use by legislation." Every engineer who has been connected with power-plant work, involving, as it does and must, the efficiency of hydraulic motors, has learned that, in order to determine in a satisfactory way the quantity of water used, it is wise, if not positively necessary, to specify how the water is to be measured. When, as is the case these days, "bonuses and forfeits" involving thousands of dollars are based on variations of discharge as small as one-tenth of 1%, as stated by Mr. Williams, it is certainly advisable, by legislation or otherwise, to fix some one standard form of weir measurement. In such a case it is as important, perhaps, to get uniform results as to get results which are accurate.

Mr. Smith says, "The best method for a particular case depends on the surrounding conditions." The writer holds that the best method for all cases is that by which the same quantity of flowing water can be measured again and again by different trained observers, each measurement giving the same result. This is especially true if the result is an accurate one.

That the Utah law establishing uniform cross-sections for roads is an unwise one is a fact that has no bearing on this discussion.

Results Inaccurate When not Based on Experiment.—Can Mr. Smith know, or can he or any one else find out, at any reasonable cost, what degree of accuracy he obtained when measuring water with the special weir described in his discussion? The channel of approach, he says, was "scoured out to a depth of from 1 to 2 ft." Thus great additional uncertainty was introduced into the results.

Mr. Lyman

Modified Venturi Meter.—The writer agrees with Mr. Smith that "in the western part of the United States it is likely that a modification of the Venturi water meter will come into use to a considerable extent." Experimental data on a device of this sort will be welcomed.

Undershot Weir.—Another device, which may be used with great satisfaction in the near future, is the "inverted weir" without end contractions, that is, a notch in the bottom of a diaphragm across the channel, with contraction at the top only. Through such a notch or under such a "weir", sediment would pass readily. In order to make this structure a very valuable measuring device, it only remains for some one to determine the relation between the quantity of water flowing through the notch and the difference in elevation between the surface of the water above and the surface of the water below the diaphragm.

The Cippoletti or the Suppressed Weir?—Mr. Jarvis writes:

"If a single type of weir were adopted, either the Cippoletti or the sharp-crested rectangular weir without end contractions would doubtless serve best in irrigation practice."

For accurate work, where measurements are to be taken over comparatively long periods and under varying conditions, practically every good reason is in favor of the suppressed and against the Cippoletti weir.

Weir for Quick Rough Work.—A case cited by Mr. Jarvis is a good one in favor of the Cippoletti weir; that is, where a portable device of this sort is used by a ditch rider. When such rough and hurried measurements give the accuracy desired, it may be wise to use the Cippoletti weir.

Measuring Flume and Current Meter.—Mr. Jarvis draws attention to the use of the measuring flume and the current meter. In canals where the slope is slight, these can be wisely used.

Maximum Discharge, Minimum Obstruction.—The writer is grateful to Mr. Jarvis for the clear statement that "the rectangular weir without end contractions provides the maximum width of crest, and the minimum obstruction to the flow in the canal."

Difficulties Encountered in Accurate Measurement of Heads.—The value of this paper is greatly increased by the keen comments of Professor Williams. He points out errors which are introduced into weir work through inaccuracies in measuring heads. He also presents much original matter relating to differences which occur when the same head is measured on the same weir at the same time by different persons and in different ways. He points out specifically the difficulties encountered when an attempt is made to measure heads carefully.

Conclusion.—In conclusion the writer could hardly do better, perhaps, than refer to the six reasons given near the beginning of this

Mr. Lyman.

paper setting forth the advantages in practice of using weirs without end contractions. In the language of Mr. Jarvis, these weirs "provide the maximum width of crest and the minimum obstruction to the flow in the canal." This is a vital matter where streams carry great quantities of silt.

New practical features added since the paper was written are the use of flush-gates in the bulkhead which carries the permanently fixed crest (Figs. 50 and 51); suggestive definite dimensions for weirs to be used for measuring certain quantities of water, and the quantities of concrete required to build the structures recommended (Table 71); and a table giving discharges over all sharp-crested weirs without end contractions within the limits of experimental data (Table 69).

The writer is more strongly convinced than ever that when irrigation engineers and practical hydraulicians have given careful consideration to the matters contained herein they will agree with him that, for general application, where accurate practical information is wanted, and where any weir can be used for measuring water, that without end contractions will answer the purpose best.

TOPOGRAPHICAL SURVEYS MADE BY THE AMERICAN SECTION OF THE INTERNATIONAL BOUNDARY COMMISSION UNITED STATES AND MEXICO.

Discussion.*

By W. W. Follett, M. Am. Soc. C. E.†

W. W. Follett, M. Am. Soc. C. E. (by letter).—Owing to illness and absence from his office, where all his records are kept, the writer can only review the discussion of this paper briefly. The interest shown by the members in the subject has been gratifying. Mr. Follett.

Mr. Landreth brings out quite plainly the relation between the number of shots per square mile and the cost. His figures, however, as would be expected, show that the cost does not increase in direct ratio to the number of shots. With 15 times as many shots as on the work described by the writer, his cost was only 4½ times as much per square mile. Of course, conditions as to brush, etc., may have affected the relative cost of the two pieces of work.

After further study, the writer is inclined to agree with Mr. Brown that he set the maximum errors too high, and will modify his statement on that subject to read:

"In any work where a variation of ½ m. to 1 m. in the relative location of points near together, or 3 or 4 m. in that of those which are material distances apart, can be tolerated, the stadia offers a most rapid and handy method of work."

Beyond this, he cannot go. The Cincinnati surveys must have been most thoroughly controlled by triangulation. Even then, the writer does not see how a map could be made, which would scale so closely

* Continued from February, 1914, *Proceedings*.
† Author's closure.

Mr. Follett.

under all conditions of weather. He has found that map paper swells when the air is moist and that the swelling crosswise of the sheet may be twice that lengthwise, so that the map is distorted and measurements of long distances cannot be checked to the limit mentioned of "$\frac{1}{80}$ of an inch".

The rod used permitted of accurate readings, under good atmospheric conditions. The work was not done in a slipshod manner, as might be inferred from Mr. Brown's remarks. Certain standards, which were considered proper for obtaining data for a map of 1 in 5 000, were adopted and enforced.

The writer regrets that he did not note the table on page 235 of General Barlow's report, and reproduced by Mr. Smith, as Table 25. He took the distances between monuments from the official report, signed by all six commissioners—three on each side—supposing them to be correct. It is gratifying to know that his chaining was so good.

Two of the Brandis transits used on this Barlow work fell to the writer, and he used them on an extensive survey of the lower Rio Grande in 1897-98. They were a source of constant worry, as the stadia wires would vary slightly in their intercept and in neither was the interval 1 to 100, nor was the middle wire half way between the other two. Frequent interval determinations were necessary.

The use of the needle, as suggested by Mr. Smith, does not appeal to the writer, except for very rough preliminary surveys. He does not believe that any man can read a needle closer than to 5′ of arc, and his error may be 10′, and an error will be introduced which is many times that which arises from the neglect of $f + c$. The diurnal variations will also affect the needle readings. This may do for very rough work, but not where a fair degree of accuracy is desired.

It was not the writer's intention to intimate that he sent instruments to the makers for adjustments other than that of the stadia wires. In fact, he has never sent an instrument to the maker for any adjustment. If the stadia wires did not subtend 1 in 100, he used a reduction table. He merely suggested the expediency of having wires reset.

The point in the paper most criticized was the ignoring of $f + c$ and the absence of interval determinations. The writer should have stated that the intervals of the transits used on the stadia work were tested at the beginning and at the close of the survey, and that one, with which the instrumentman did not get as good closures as the other men, was tested two or three times during the progress of the work.

Assuming that $f + c$ is to be ignored in the field work, the writer would enquire how a man is to proceed to make a reduction table when, the hubs having been accurately set by steel tape 50 m. apart and the transit set up $f + c$ (which was, for the transits used, if the writer's

memory serves him, about 0.3 m.) back of the first hub, the instrument-man states that he reads exactly 50 cm. on the 50-m. hub, exactly 1.00 m. on the 100-m. hub, etc., and when the other men present, including the writer, check these readings? Three of the five transits used on the survey gave this result. It was known that the intervals of the other two were not 1 in 100 but, as they were not to be used on stadia work, their intervals were not determined. Mr. Follett.

As for the ignoring of $f + c$, the results given in the paper, in the writer's opinion, are sufficient to show its expediency.

The writer agrees with Mr. Brown that the quoting of cost data on any work, stadia or other, is a dangerous proceeding unless all the conditions are fully stated, and that even then it may be misleading. It was the intention to compare the cost of this with similar work. He cannot, however, imagine any case where he would feel justified in spending from $1 000 to $2 000 per sq. mile, or even the first amount, on a stadia survey. If property is so valuable that such an expense in making a survey of it is justified, then some method more accurate than stadia should be used.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

Discussion.*

BY MESSRS. FREDERIC V. ABBOT, J. F. RAMSBOTHAM, AND HARRISON SOUDER.

Mr. Abbot.

FREDERIC V. ABBOT, M. AM. SOC. C. E. (by letter).—Mr. Rippey's discussion† is exceedingly interesting, because it carries to much further length a method adopted by the writer in 1899, in constructing a cut-off wall of moderate depth at Lock and Dam No. 2, Mississippi River, between St. Paul and Minneapolis. At this locality the material forming the bed of the river was a very hard combination of clay, sand, and limestone fragments, mixed with a few granite boulders, overlying the well-known, friable sand rock of this part of the Mississippi Valley.

Fig. 19, shows the nature of this material, which underlaid the lock floor and the lock walls. A description of the difficulties encountered in handling this material, which is quickly eroded by rapidly flowing water, and of the methods adopted to overcome them, is given in the following extract quoted from the writer's Annual Report to the Chief of Engineers, U. S. Army, dated July 17th, 1900:

"The seams were all originally water-bearing, and only became dry after long pumping had drained out all the water tributary to them. At a lower level these seams run out into the bed of the river, and in this way passages for water are opened between the river bed and the interior of the cofferdam, many feet below the original bottom of the river at the point where the cofferdam stands. It had been realized from the start that such seams were to be encountered, and to avoid opening up too great a flow at any one time a novel form of cut-off wall was adopted after prolonged study. A slot in the sand rock is made, 2 inches wide and 12 feet long, parallel to the river wall and lying between two longitudinal foundation timbers, by jetting

* Continued from April, 1914, *Proceedings*.
† *Proceedings*, Am. Soc. C. E., March, 1914, p. 779.

Mr. Abbot.

a series of intersecting vertical holes 10 feet deep and breaking off any projecting edges between the holes. Most of the eroded material is brought up out of the slot by the jet, and the rest is easily pumped out with the ordinary Edson diaphragm pump and two men. In the usual case this leaves a perfectly clean slot with a considerable flow of water pouring out of it, the water coming from the underground seams which connect with the river. Into this slot a diaphragm made of tongued and grooved three-quarter-inch boards, in two layers breaking joints, is lowered by hand. Three vertical 1½-inch iron pipes, extending down into the slot only a few inches, are inserted, one at each end and one at the middle of the slotted section. A steam pump connected to one of these pipes is now started just fast enough to take care of the flow from the slot without letting it run over, or draining it below the level of the surface more than a few inches, and concrete is rammed into the space above the slot and between the foundation timbers above referred to, which have been firmly drift-bolted down to the sand rock before the slot was cut. As soon as the concrete has set—that is, in about twenty-four hours—the pump is stopped, and water at once flows out of all three pipes. Additional lengths of pipe are screwed on the three till the flow is stopped—that is, till the tops of the pipes are at a higher level than the head due to the pressure in the seams. Thick grout is now poured into smaller pipes passing through the first pipes and reaching to the bottom of the slot. As the latter fills with grout the water is forced back into the seams. The small pipes choke after the grout rises a couple of feet above their lower ends, and they are then raised till they again flow freely. When the slot is full they are removed and the larger pipes are kept filled to the top with the grout as long as any more can be poured in. After about twenty-four hours all the grout has hardened, the pipes are removed, cleaned out, and used over again in another section of cut-off. (Photographs Nos. 7, 8, and 9* show an experimental section of such a cut-off wall which was put in at a high level in the lock pit and then carefully excavated.) The perfect grout filling of the most minute

Note on Fig. 19.—The extreme friability of the material is shown. The method of supporting the timbers on this unreliable material is shown at the top of the picture. The timber is wedged up on wooden blocking so as to leave a space of about 2 in. between it and the surface of the sand rock. The anchor-bolts are then driven and the wedges removed, leaving the timber supported on the anchor-bolts. The surface of the sand rock is then thoroughly washed with water from a hose, all loose matter is removed, and the space between the fresh sand rock surface and the timber is filled with good concrete rammed in place with heavy sledges and steel followers.

Note on Fig. 20.—The two large timbers between which the concrete is seen represent foundation sills. They are fastened to the sand rock every 4 ft. by the 1¼-in. drift-bolts, of which one is seen extending down into the wooden pin, a part of which has been removed. These bolts extend 3½ ft. into the wooden pins, and require a force of more than 9 tons to withdraw them. The wooden pin to the left is shown encased with grout, as it was when the sand rock was carefully removed from around it. The narrow white column about half way between the two pins is the end of the cut-off wall as it appeared when the first 2 ft. of the sand rock was removed. The white marks, looking like splashes of whitewash, are really thin filaments of grout which had penetrated the seams in the sand rock, showing that the cut-off wall is not only a thin impervious vertical curtain in the sand rock, but that the latter itself is solidified for at least 2 ft. on each side. The board in a horizontal position under the concrete is used to prevent the fresh concrete from falling down in the slot alongside of the board curtain, and thus preventing the grout from having a thorough subsequent circulation.

* Reproduced herein as Figs. 21, 20, and 22, respectively.

FIG. 19.—VERTICAL FACE OF SAND ROCK ON THE LOWER SIDE OF THE EXCAVATION FOR THE UPPER LOCK GATE AND CULVERTS.

FIG. 20.—EXPERIMENTAL SECTION OF CUT-OFF WALL, PARTLY EXCAVATED, TO DETERMINE WHETHER THE GROUT FILLED ALL CREVICES, ETC.

cracks in the sand rock is surprising. An absolutely tight cut-off wall from the bank above the lock to the outer toe of the river wall, and under this toe for its full length and back to the bank below the lock, extending to a depth of 23 feet below dead low water in the river, or deeper in that part under the river wall, is thus secured. Mr. Abbot.

"In some cases no subterranean seams are encountered, and then the wooden diaphragm is inserted and the grout at once poured in around it through pipes leading to the bottom. Experience has shown that in such cases time is a vital element. A slot which does not develop the least flow at first, has in several cases developed very great and troublesome flow in twenty-four hours if not grouted. Most trouble was encountered at the upper end where a very large seam directly connecting with the river had to be cut off. This seam extended nearly horizontally under a space fully 30 feet wide by 80 feet long, and every section of cut-off wall intersected it. Grout poured into one section would pour out of another 30 feet distant. As these underground connections were not suspected, the quantity of water which poured out of three openings into this seam soon exceeded the capacity of the pumps. All arrangements for grouting two of the three sections were completed except the stopping of the flow from the pipes, which in this case were 6-inch in diameter and were running full. It is believed to be unsafe to try to stop suddenly such a flow for fear of blowing up the lock floor. The cofferdam was allowed to fill, thus gradually stopping the flow from the seam, 6-inch risers were screwed into the now submerged overflow pipes and both sections were grouted at the same time from staging erected above the water level. Twenty-one barrels of dry sand cement were required for the grout to fill the slots and seam. In three days the cofferdam was again pumped out and the two springs were found stopped entirely. The third was really outside of the lock walls, being in a section of slot that had been put in to make connection with the cut-off wall under the dam. It was successfully separated from the cut-off slot under the lock wall, which has since been easily grouted."

In the preceding paragraph mention is made of sand-cement. In view of the high freight rates existing at that time between the American Portland cement factories and St. Paul, sand-cement was used in the construction of the land wall of this lock. To insure getting exactly the proportions of sand in the sand-cement, a tube mill was purchased and the cement (Saylor's brand) was ground at the lock site with a very excellent silicious sand found in the vicinity. The concrete made with this sand-cement has stood the extreme temperature conditions at St. Paul, 105° in summer to 40° below zero, Fahr., in winter, for the past 14 years in a surprisingly satisfactory manner. The river wall was built of Saylor's cement, used in the same proportions as the sand-cement in the land wall. A very sharp comparison of the two kinds of concrete has thus been secured. Although the writer has not been able to inspect the work, he has been told by those who have, that the concrete in the land wall is, if anything, superior at the present time to that in the river wall. For

Mr. Abbot.

the land wall, the cement was ground with an equal proportion of sand, by volume, and the sand-cement thus produced was used in the same ratio to unground sand and broken stone as if it had been regular Saylor cement.

In connection with the construction of this lock, a great deal of grouting of seams similar to that described was necessary, and in this work great economy resulted from the use of sand-cement in place of undiluted Saylor cement. Experiments were made in order to determine whether sand-cement applied in the shape of grout would harden. A vertical glass tube, 4 or 5 ft. long and about 1 in. in diameter, was plugged at the bottom and filled with a 1 to 1 sand-cement grout and allowed to harden. The tube was broken in 3 days, and it was found that the lower part of the grouting in this pipe was as hard and sound as that at the top. When ordinary sand was mixed in the same proportion with undiluted Saylor's cement, kept thoroughly stirred up, and poured into a similar tube, the sand settled to the bottom very rapidly, leaving a creamy grout with hardly any sand grains in the upper part of the tube. Under these conditions the bottom 2 ft. never set, though the upper 2 or 3 ft. set about as hard as the sand-cement grout did in the other tube. The reason is plain. The specific gravity of cement clinker is not widely different from that of silica. When the silica is in large grains, and the cement clinker is ground fine to make a Portland cement, the two materials separate in water, the larger particles settle quickly and reach the bottom first, and the finer particles, which settle less rapidly, remain near the top of the column. Since making this experiment the writer has always had considerable doubt as to results of grouting with Portland cement stirred up with ordinary sand, but he has no doubt of the effectiveness of grouting with sand-cement ground 1 part of cement to 1 part of silicious sand, provided the grinding is carried far enough to make the sand as fine as ordinary Portland cement. From Mr. Rippey's description, the writer supposes that no sand was incorporated in his grout. If sand-cement had been used, it would seem, therefore, that the cost of grouting might have been somewhat reduced provided the freight rates to the Estacada Dam were high enough to make it pay to install a cement-grinding tube mill.

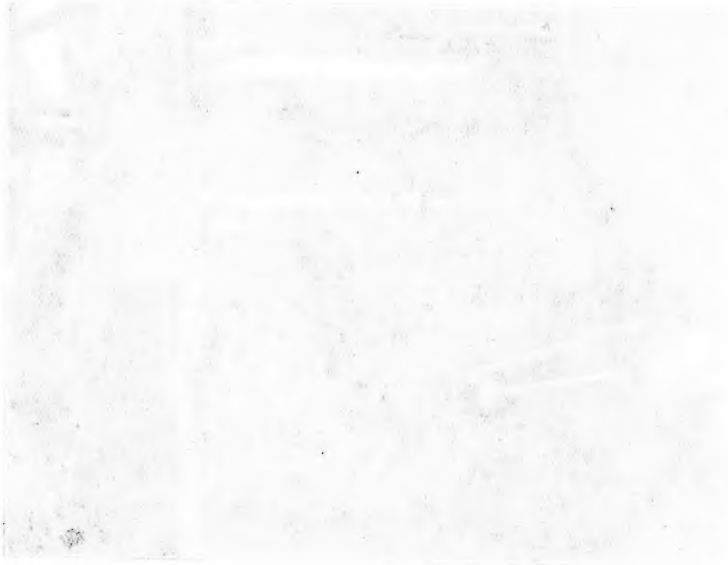
Note on Fig. 21.—The complete covering of the end of the wooden curtain by the grout is well shown, as well as the way in which the latter filled every irregularity in the end of the original slot. The grout was about 1 week old, and was at the time firm and hard. It was composed of sand-cement ground in the proportion of 1 sand to 1 Saylor's Portland cement. The extreme wetness of the sand rock is well seen in the pond of water at the foot of the section. Though there was no regular flow, the water was oozing from all the pores of the face exposed by the excavation.

Note on Fig. 22.—At the top, the grout covering the end of the diaphragm has been removed to show the boards, and, in the middle of the plane parallel to the diaphragm, the grout has been scraped off to show the flat side of the boards. The rest of this plane is left as it stood when excavated, showing that the grout absolutely holds the sand rock to the boards. The irregular projections at some points in this plane show where there was originally a seam in the sand rock, which has been filled by the grout.

EXPERIMENTAL SECTIONS OF CUT-OFF WALL.

FIG. 21.—WHEN EXCAVATION HAD PROGRESSED TO A DEPTH OF 6 FEET.

FIG. 22.—A SECTION PARALLEL TO THE DIAPHRAGM OF BOARDS, AND A FEW INCHES, ONLY, FROM IT.



J. F. RAMSBOTHAM, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with great interest and is of the opinion that it will be of value to the entire Profession. He would like to draw some conclusions based on his experience gained on the Fremantle Graving Dock.* Mr. Ramsbotham.

In the first instance he differs with the author in regard to the method of starting with a low pressure of 25 lb. and ending with a pressure of 250 lb. per sq. in. Surely the pressure should have been higher in the initial stages, for, with the depth of hole in use, there was no fear of doing damage, and, at the same time, a better and more pronounced penetration would have been assured.

A pressure of 250 lb. per sq. in., or 16 tons per sq. ft., is certainly very high, and the quality of the rock must have been exceedingly tough to have withstood it. The danger of using such a pressure is considerable, but risk of damage would be lessened by having other holes drilled in the vicinity of the grouting, such holes acting as a safety valve.

The author's summary of the advantages reaped is somewhat disappointing.

From the writer's experience, cement grouting can be relied on to form a cut-off from percolation water, and this experience was gained by witnessing daily a material decrease in pumping.

The holes should be staggered, the front row being 6 ft. from center to center and the back row 3 ft. back from them. The writer considers it preferable to drill the front row first and then check and test the results by the back row, but it is quite impossible to lay down any hard and fast rule. Each case must be judged on its merits.

The whole question of efficiency is problematical, and for that reason, before adopting cement grouting and giving a positive opinion, an actual inspection of the site is desirable.

As regards fortifying bad ground (such as a gravel bed) to withstand a heavy statical load, the writer has no hestitation in saying that by cement grouting this can be done economically and safely, there is no excavation to make and replace with concrete, and no pumping.

HARRISON SOUDER, M. AM. SOC. C. E. (by letter).—It is a fact that very little has been published in regard to the treatment of foundations by the use of cement grout. The interest manifested in the Estacada work causes the writer to regret deeply that his experiences in this line some 13 years ago, were not given to the Profession at the time. However, the identical method of securing a tight cut-off wall—by injecting a cement grout under pressure through drill holes, as described by Mr. Rands—was used by the writer in the construction of the Hinckston Run Dam at Johnstown, Pa., as long ago as 1901. Mr. Souder.

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 1942.

Mr. Souder.

The fact that this method of grouting was used in the foundations of this work prior to the Estacada operation is brought out in a brief description of the Hinckston Run Dam published in 1909 by the late James D. Schuyler, M. Am. Soc. C. E.*

At the time this method was adopted at Johnstown, the only information the writer had on the subject was that gained from watching the grouting of the tunnel backing of the deep sewers built in connection with the Pennsylvania Avenue Subway and Tunnel and in closing leaks in the Torresdale Conduits, in Philadelphia; and especially from a report† by F. V. Abbot, M. Am. Soc. C. E., Major (now Col.) Corps of Engineers, U. S. A., Engineer in Charge of Improvements of the Mississippi River at St. Paul and Minneapolis. The report describes an extremely interesting method of forming a tight cut-off wall by using cement grout, exactly after the method suggested by Mr. Rippey on page 779‡ and illustrated by Fig. 16, except that the diaphragm was made of wood and the grout was applied under hydrostatic pressure sufficient to overcome the head of the water flowing through the rock seams.§

As the work at Johnstown was in the seamy shales of the soft-coal formation, a detailed description of the cut-off wall may be of value even at this late day. To add to the clearness, and as a matter of record, a brief description of the dam is given.

The Hinckston Run Dam.

In 1900 the Manufacturers Water Company, after a comprehensive study of the problem of increasing the water supply of Johnstown, Pa., and the rapidly expanding plant of the Cambria Steel Company, determined on the construction of several large reservoirs and pipe lines.

In view of the frightful calamity of 1888, caused by the breaking of the South Fork Dam, there was naturally much opposition to the construction of any new dams above the city. Under the direction of Mr. John Birkinbine, as Consulting Engineer, the first of the proposed reservoirs was located 5 miles from Johnstown, on Hinckston Run, a stream which flows into the Conemaugh a short distance below the famous Stone Railroad Bridge. All the streams in this district are essentially mountain streams. The valleys are narrow and the hillsides steep and rocky, and therefore the run-off is rapid. The average yearly rainfall is 36 in., but it is not well distributed, the major part coming down in the winter and spring; though some extremely heavy and sudden downpours occur in the summer.

† An abstract of this report was published in *Cement*, January, 1901.

‡ *Proceedings*, Am. Soc. C. E., for March, 1914.

§ The reader is referred to Col. Abbot's discussion, which contains an extract from his report, and several illustrations.

Mr. Souder.

The original Hinckston Run project called for an earth dam, 60 ft. high, to retain some 400 000 000 gal. of water, with a depth of 45 ft. at the breast.

The intention, as stated, was to build a dam 60 ft. high, with a clay core, but, as an unlimited quantity of cinder from the steel plant was available, it was decided, after the work was started, to use this as backing for the dam, in place of earth, and eventually to fill the whole valley below with this material, thus rendering the structure practically unbreakable. In view of this and the additional expense incurred in making the cut-off tight, the proposed height of the dam was increased to 80 ft., and later to 85 ft., above the original creek level. This gave a total maximum height above the bottom of the core-wall ditch of 112.8 ft., a depth of water at the breast of 73½ ft., and a capacity of 1 100 000 000 gal. The lake thus formed is 1¼ miles long. The water-shed above the dam is 10.75 sq. miles.

With the consequent great increase in pressure, extra care was needed, and every precaution was taken to make the structure water-tight.

The site selected for the dam required a rather long breast, but gave an excellent opportunity to construct a spillway with natural rock bottom, and was close to several large deposits of excellent clay lying within the reservoir site.

Work on this dam was started in the fall of 1900. The writer took charge as Resident Engineer and Superintendent of Construction early in May, 1901. At that time the dam site had been cleared of timber and partly stripped, and a small section of core-wall ditch had been excavated to a depth of 12 ft.

The first work done was to strip the surface of the dam site of all soil and vegetable matter. This was generally 3 ft. deep, but over a large area, near the creek channel, it was necessary to remove material to a depth of 8 or 9 ft. owing to numerous beds of muck, old logs, etc. All this material was deposited in the rear of the embankment proper. The remainder of the reservoir area, some 105 acres, was cleared of all timber and brush, but the surface soil was not removed, as the water to be stored was intended for mill purposes only.

Work on the dam proper was suspended on rainy days and during the winter.

The cross-section of the dam as built is shown by Fig. 23. The lower inner slope is 1 on 2¼, with 4 ft. of puddle and 24 in. of cinder rip-rap. The slope above the berm is 1 on 1¾ with puddle lining diminishing to 2 ft. thick at the top. The facing is hand-laid stone paving. The puddle wall is 16 ft. thick at the top of the concrete core-wall, and diminishes to 4 ft. at the top of the dam.

Early in July, 1901, when the core-wall ditch had been carried down to hard rock at what was thought to be the proper depth, some test

Mr. Souder.

holes were bored through the bottom to determine the character of the rock below. This disclosed a layer of hard sandstone a few feet down, with considerable water flowing below and above it. It was decided to deepen the ditch considerably, in order to get below any rock strata that might come to the surface within the flooded area, and to substitute a concrete core-wall for the clay one originally proposed.

An air compressor plant was installed. This was a 14 by 18-in. Ingersoll-Sergeant machine capable of driving two rock drills and six pneumatic rammers. These rammers were used in tamping concrete and also in puddling clay in such places as could not be covered by a 10-ton steam roller which was also supplied at this time in place of the 3-ton horse roller in use.

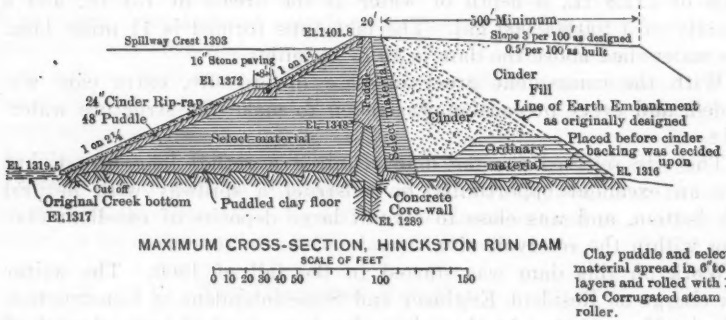

FIG. 23.

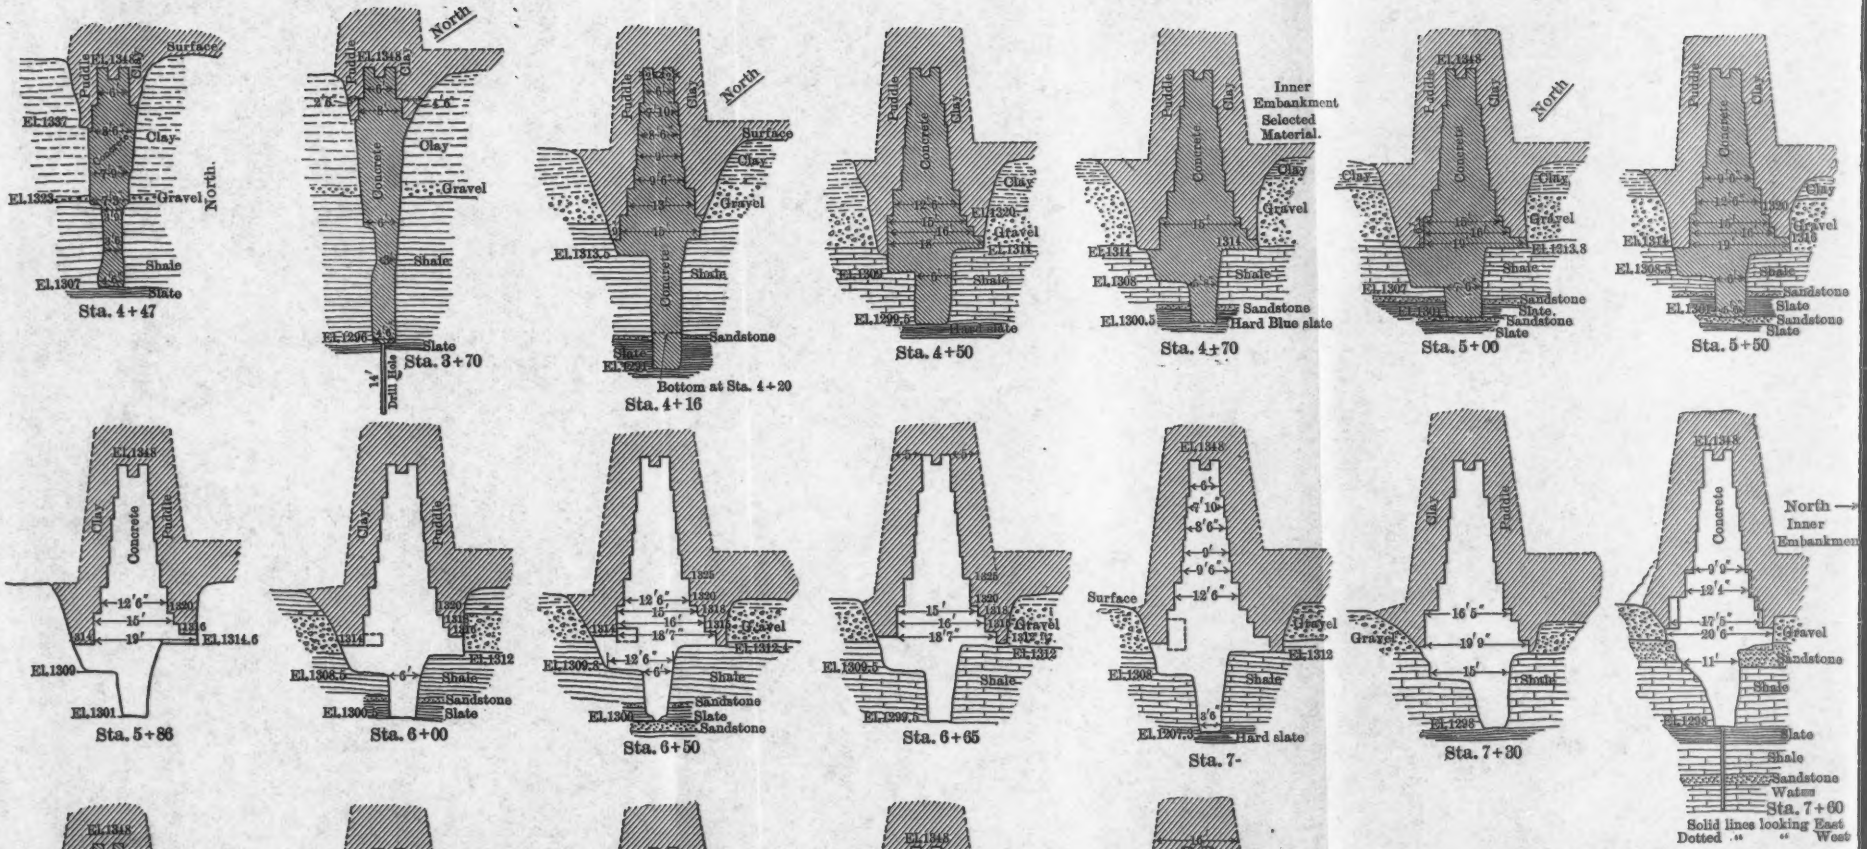
The finished ditch averaged in depth 25 ft. below the grubbed surface in the valley, but reached 50 ft. at the ends. The shale was excavated with picks, but the harder rock was loosened with light charges of dynamite, care being taken not to shatter the foundation or open up the seams. Plate XII shows typical sections through the core-wall and ditch, the variable character of the strata cut through being indicated. The advisability of cutting off the underflow to as great a depth as possible was realized, and it was determined to remove the shale down to the sandstone and try to cut off the flow below by forcing in cement grout under air pressure.

Drill holes, 2 in. in diameter and from 10 to 16 ft. deep, were drilled through the rock, averaging about one hole per linear foot across the valley. Iron pipes, 2 in. in diameter, 18 in. long, and threaded on one end, were cemented into these holes. Portland cement grout was poured into them and then air at a pressure of from 30 to 60 lb. was applied.

The first holes were approximately 6 ft. apart. They were drilled generally 10 ft. below bed-rock. The first hole drilled was marked No. 1 W., the second No. 2 W., 5 ft. distant, the third No. 4 W., 17 ft. distant.



Note- Drill holes 2" diam. in bottom of ditch; 10 to 16 ft. deep between Stations 3+60 and 8+00; and 6 to 10 ft. deep between Stations 8 and 8+70. Cement grout forced into these holes under 60 lb. air pressure.

Mr. Souder.

After No. 1 was grouted, a small pit, or sump, was excavated through bed-rock and into the shale below. Signs of grouting were visible 2 ft. below the sandstone, which was encouraging. After some twelve holes had been drilled within a distance of 66 ft., an effort was made to determine the location and extent of the water seams below bed-rock by using a solution of permanganate of potash. In a letter to Mr. Birkinbine, dated July 22d, 1901, the writer described this test as follows:

"In the main core-wall ditch I made some tests to determine the location and length of seams under bed-rock. Mr. Hyde, the Cambria Chemist, brought some potassium permanganate out. We put several buckets full of the solution into the receiver and connected it with hole No. 3 West and then turned on the air. The color showed in the sump and in holes Nos. 4 and 5 and slightly in No. 6, entering the last hole at least 2 in. from the surface. This showed that 2 in. and 3 in. of shale had not been stripped from bed-rock, also that the seam extended from No. 3 hole beneath bed-rock to the sump. This test was not altogether satisfactory, so we put a pipe in No. 6 W. hole, from which a strong clear stream of water flows. Put some permanganate in the tube and connected the air hose directly to the tube. The color showed in Nos. 4 and 5, in fact, as far as the sump. About this time the pump valve got out of order and the water rose in the trench, covering most of the holes. Then I put on full air pressure, and after a time it began to appear all along the trench bottom from the sump to hole No. 12. Up to No. 10 it was very distinct, at Nos. 11 and 12 the effect was not quite positive. Keeping the pressure on, I had the sump drained, and found the air blowing in at the bottom and on the far side and lower side.

"Evidently there are seams underlying the length of bed-rock. The small *y*'s on the following diagram [Fig. 24] indicate where the air blew out."

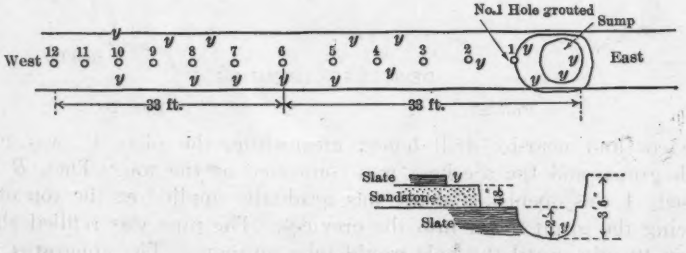

FIG. 24.

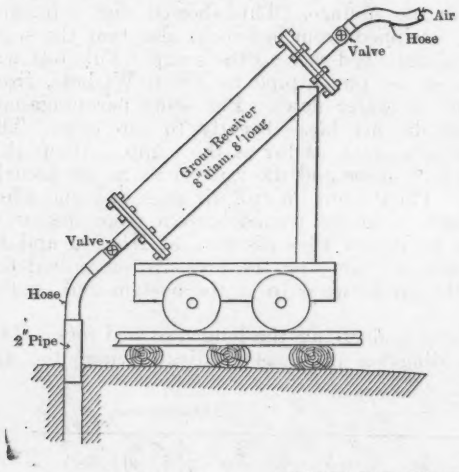
Fig. 25 is a sketch of the first contrivance or receiver devised for applying the grout. It was a cylinder, 8 in. in diameter and 6 ft. long. A screw flange was provided at top and bottom, and a steel head-plate was bolted to each end, with rubber gasket packing. The top bolt holes were open to allow quick removal of the lid. A 2-in. pipe with plug cocks was provided at the top and bottom. With a short hose, the cylinder was coupled to the pipes in the holes. The

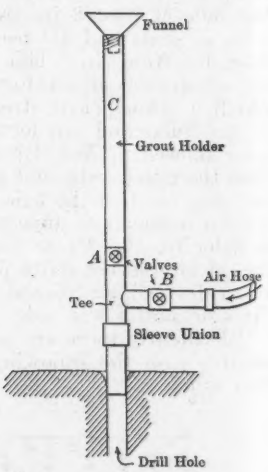
Mr. Souder.

cylinder was filled with grout; the valve was opened; the grout ran into the drill holes, and air pressure was then applied at the top. The contrivance was mounted on a truck running on a track in the bottom of the ditch. After trial it proved to be too slow and cumbersome, and another method was devised and operated satisfactorily. Fig. 26 is a sketch of this final arrangement, and Fig. 27 shows it in operation.

The method of grouting was as follows:

A 1-in. pipe, long enough to reach to the bottom of the hole, was inserted and air was applied to blow out water and dirt. Then a tee and the pipe, *C*, were attached to the tube in the drill hole with a sleeve union, as shown. The cock, *A*, was closed, the cock, *B*, was opened, and air was applied, thus forcing the water out of the hole and into the





DEVICES FOR GROUTING

FIG. 25. FIG. 26.

crevices and near-by drill holes; meanwhile, the pipe, *C*, was filled with grout, and the air hose was connected at the top. Then *B* was closed, *A* was opened, and air was gradually applied at the top of *C*, forcing the grout down into the crevices. The pipe was refilled about every 10 min. until the hole would take no more. The apparatus was then removed and a cap was screwed on the tube in the grouted hole. After a given length of ditch was grouted in this way, and sufficient time had elapsed to allow the grout to set, test holes were bored within the grouted area and the process was continued until there was no indication of water flow below the bottom. The greater part of the bottom was grouted successfully in this way, but, as explained later, the grouting scheme was abandoned where the core-wall ditch entered the side-hills.

FIG. 27.—METHOD OF GROUTING UNDERLYING SEAMS IN CORE-WALL DITCH. GROUTED HOLE WITH CAP, IN FOREGROUND. CEMENT PLASTER ON SIDE-WALLS OF DITCH.

Descriptive of this work, the following extracts from reports by the writer, made at the time, may be of interest: Mr. Souder.

EXTRACTS FROM REPORTS ON GROUTING TESTS.

July 12th, 1901.—"Finished drilling second drill hole. Strip rock near first hole. No signs grout at 3 ft. distance."

July 13th, 1901.—"Excavated to hard rock and then drilled holes every 6 ft., 10 ft. deep. (Later, 16 ft. deep.)

"Cut away 18-in. layer of rock to within 2 ft. of first drill hole grouted and discovered evidences of grouting. Two of the new drill holes flowed water, which on test comes mainly from within 3 ft. of surface of rock."

July 17th, 1901.—"Test of setting of grout; after 2 hours the neat cement grout hardly set enough to resist anything like a current of water. Addition of sand helps it. Recommend quicker-setting cement."

August 3d, 1901.—"There is a thin layer of shale and slate on the sandstone at Hole No. 11 E. becoming thicker to the east at Hole No. 20; the sandstone is 6 ft. below the shale. This explains why water is found at two levels. On No. 19 E. we had water at 4 ft. and again at 15 ft. To-day grouted several holes. The first was No. 13 W. From this hole a fairly strong stream was flowing out of tube 12-in. high. I first forced air in the hole without cement. Air bubbled out of Hole No. 11 W. very weakly but quite strongly from Nos. 12 W., 14 W., 15 W., and 19 W. Made a smooth-flowing grout of 2 bags cement, 1 bag very fine screened sand, and 3½ buckets water. After the air had been on 30 min. a strong cement color appeared in Hole No. 15 and weaker color in Hole No. 14. Kept pressure on for 1 hour. The grout appeared rather soft in the hole, and after a time a very small thread of water came through it. Flow of water from No. 12 did not diminish appreciably, but carried slight cement color. Difference in level of grout in cylinder, before and after, 5½ in. Next grouted No. 11 W., forcing in 3¼ in. of grout after ¾ hour pressure, there was no perceptible difference in flow from adjoining holes. There was no water flowing from No. 11 before grouting. Hole No. 8 took 2½ in. of grout after ¾ hour. No water flowing from the hole before grouting."

August 6th, 1901.—"In the core-wall ditch we have now 13 holes grouted. To-morrow I will move the drill back and put in some intermediate holes to test the grouting. I must arrange in meantime to drain the east end of the core-wall ditch in order to uncover the sandstone, which dips rapidly into the hill. The shale, being more than 6 ft. thick, is giving considerable trouble to the drillers, so think it advisable to suspend drilling in the east end of the core-wall ditch until the sandstone is uncovered. The following is a description of grouting of holes mentioned in letter of last evening:

"Hole No. 4 W.: water standing in tube about 1 ft. high. Cylinder with grout placed and air on for 1 hour. Valve on tube closed for ¾ hour longer. Hole contained 2 ft. cement in bottom, with water above. Rammed thick mortar into tube and put on pressure again for ½ hour, 8½ in. of grout went into the hole.

Mr. Souder.

"No. 2 W.: no water flowing from this hole. Connected air hose directly to the tube, forced the water out of the crevices. Then poured in two buckets of grout (1 cement, 2 sand) after having air pressure for ½ hour, the grout had settled in the hole 2 in.

"No. 12 W.: strong stream water flowing from this hole at beginning. Forced water out, the air coming out at the sump near hole No. 1 W. Put in one bucket sand and cement dry and put on air for 10 min., after which time the hole was empty. Then put in second bucket dry grout and put on air. This stopped air from coming out at the sump. The hole was practically empty. Then put in a bucket (3 gal.) of wet grout and put on air for 15 min., which left the hole plugged. Hole No. 7: no water from this hole at beginning. Pumped water out by hand-pumps. Put in a bucket wet grout, and after pressure on 15 min. the grout had settled 2½ in."

Again, on September 9th, the writer stated:

"The core-wall ditch, where the pipe line crosses, is coming into a very hard and tough stone, massive, with little evidence so far of stratification or cleavage planes, and but little water.

"In the main core-wall ditch appearances are not so pleasing, I have had four test holes driven.

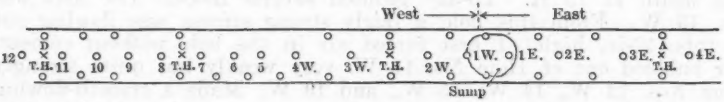


FIG. 28.

They are marked A × T. H. [on Fig. 28]. There was a considerable flow of water from all of them; least from B, and the strongest from C and D. Water was struck in all these holes between 11 and 16 ft. Putting air on at A, it came up at the sump, also through crevices in the bottom of the core-wall ditch near A, also in test holes, B and C. Test hole, D, was not finished at the time. Hole A took 8 buckets of grout; Hole 3 took 3 buckets.

"When air was on C air came out rather strongly at the sump, and at test hole, D, and from bottom of core-wall ditch between holes, T, and 6 W., 7 and 8 W., and 8 and 9 W. After putting in 4 buckets of grout and allowing to stand some time, cement got hard in the valve. Meanwhile we grouted test hole, D, took valve off C and found grout quite wet in C, and began to be forced out by air from D. Put long tube on C and filled with grout and applied air again on C. Then went back to D and fed it more grout, giving it in all 8¼ buckets. Air ceased to bubble up elsewhere.

"It would appear from these tests that we have a fairly tight bottom down to 10 ft. depth, the depth to which the middle holes were drilled. There is, no doubt, however, a considerable flow of water at 10 to 16 ft. depth.

"To expedite the work of drilling in part, and mainly because I think we will get better results in this work, I abandoned the old method of diamond spacing for the bore holes and started this after-

noon to drill the holes right in the middle of the core-wall ditch and spaced but 2 ft. apart. This will give us the same number of holes for a given length as previously, but, being closer, they are more likely to give us a continuous cut-off wall. At the same time, four holes can be drilled from two settings of the bar, as against three settings required for the old system." Mr. Souder.

This is shown by the sketch, Fig. 29.

"First position of bar, *A*, second, *B*. First position of drill on bar, *a*, second, *b*. Simply turn clamp over and reverse the drill in the clamp. I think this will be more satisfactory. Let me have your opinion."

To this Mr. Birkinbine replied:

"I am in receipt of your letter of yesterday, and read with interest your memoranda concerning the test holes. Remembering the fact that the first test holes were only 10 ft. deep, and we got more water in the deeper holes, your results would indicate to me that the section covering the shallow holes had probably been grouted about to their bottom, and that what you are encountering now is a practically continuous stratum below this 10 ft.

"I am inclined to believe that the appearance of air in the floor of the core-wall ditch is attributable mainly to crevices in the upper stratum, where the weight of the material is insufficient to resist the pressure. I think your plan of reversing the bar so as to drill two holes from one setting is a good one, but I am inclined to believe you can afford to separate the holes by more than 2 ft. Of course the holes from one setting will be but 2 ft. apart, but I think there could be an interval of 3 or 4 ft. between one pair, and the next pair. As to drilling these holes in the center of the core-wall ditch I should look for better results if, whenever a longitudinal crevice is evident, you drill close to this, *i. e.*, I would put the holes either to one side or the other of the core-wall ditch, according to the location of these fractures."

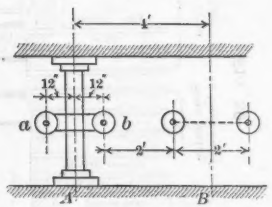

FIG. 29.

Neat cement grout was used after this, the sand being omitted. The proportion was 1 bbl. of cement to 75 gal. of grout.

At the east end three large vertical open crevices were uncovered. (Fig. 30.) The flow from these was so considerable that it was necessary to put in a force pump with a 4-in. suction and a 3-in. discharge, in order to keep the ditch clear. As the grouting method, after continued trials, did not give satisfaction at this end, it was decided to take up the bottom until the principal water strata were reached. This was done, and concrete was placed in the ditch, all the walls being plastered first with a rich cement mortar worked in

Mr. Souder.

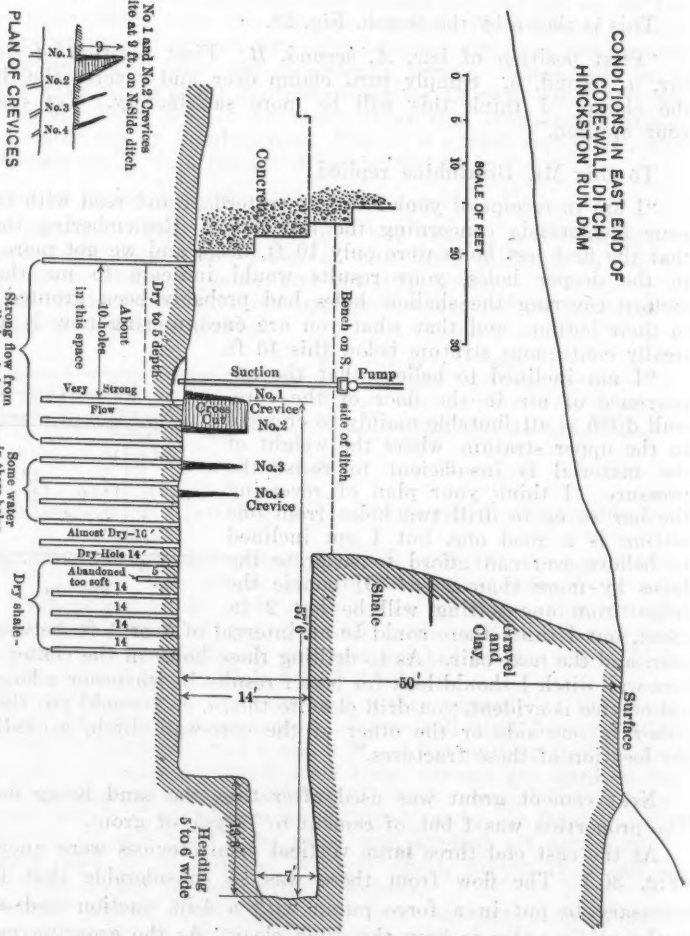

FIG. 30.

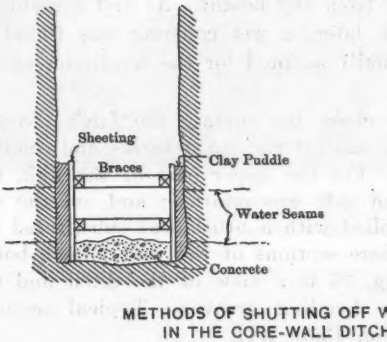
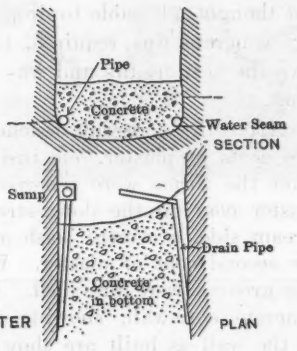
with trowels. Two coats of plaster were applied on the north or reservoir side and one on the south side. The suction pipe of the pump was built in concrete, and carried up with the wall. The strong flow of water in this section of the ditch made it difficult to place the concrete for the core-wall without having the cement washed out before it set. Mr. Souder.

At first, the method indicated in the sketch, Fig. 31, was tried, namely, a line of 1-in. sheeting was placed as shown, and clay was rammed between the sheeting and the rock to stop the water flow. Concrete was placed between the sheeting which was raised gradually as the concrete was carried up. This did not prove wholly satisfactory, and the method of piping the water directly to the sump was adopted, as shown in Fig. 32. This proved successful. Where there was too great a flow of water, plastering could not be done, but con-





METHODS OF SHUTTING OFF WATER IN THE CORE-WALL DITCH

FIG. 31. FIG. 32.

siderable neat cement was dumped in along the walls with the concrete and well worked in. After the concrete was well set, the pipes were plugged and the flow of water was shut off. As the concrete was carried up, the water came out of the ditch walls higher up, showing that the underflow had been intercepted. The core-wall ditch was extended well into the hills on each side of the valley, and test holes were bored for water, none being found, because, after a certain distance, the rock became hard and massive and free from seams. At the west end of the ditch, there was as much trouble with water. It would seem that the underflow of the whole valley was concentrated at this point, the rest of the ditch having been grouted and the flow cut off.

The drill-hole grouting method failed in the west side of the valley, as in the east, and here the bottom was also taken out, down to the water strata, and the water fought inch by inch by piping it

Mr. Souder.

from the streams to the sump, as before described, and the ditch was completely filled with concrete.

The proportion for the concrete in the core-wall was 1:2:5, generally; but, at the bottom, it was much richer in cement, which was not spared in efforts to make a tight job. Near the crevices a proportion of 1:1:2½ was used. These proportions had to be varied, also, to suit the sizes of the stone supplied, which varied from ½ in. at times to 3 in. The top section of the wall was made of 1:3:6 and 1:3:7 cinder concrete. The concrete was mixed in a machine of the continuous-mixer type consisting of a long square revolving box with a helix at the back. The machine was not wholly satisfactory, but was the best to be had. The concrete was received in ½-cu. yd. dump buckets, carried on small trucks running on light track to the derricks; it was then lowered to the bottom of the ditch and dumped, as it was not thought advisable to drop it from any height. At first a middling dry concrete was required, but, later, a wet concrete was found to give the best results and was finally adopted for the remainder of the work.

After the core-wall reached above the surface the faces received two coats of plaster, one inside against the wood forms and another after the forms were removed. For the upper part of the wall, the plaster coat on the down-stream side was omitted; and, on the up-stream side, a cement wash applied with a brush was substituted for the second coat of plaster. Where sections of the wall joined, bonding grooves were provided. Fig. 33 is a view of the ditch and the concrete core-wall, showing the bonding grooves. Typical sections of the wall as built are shown on Plate XII.

The concrete core-wall contained 10 840 cu. yd., and required 13 166 bbl. of cement, or an average of 1.21 bbl. per cu. yd. The grouting and plastering took 2 078 bbl. of cement, in addition. The exact quantity of cement used in grout alone is not known.

That the work was successful was shown by the breaking out of some small springs on the inner side of the reservoir at or about the elevation of the top of the core-wall.

The comparatively low pressure of 60 lb. was insisted upon, because it was thought that extreme pressures might do harm in opening up the seams unnecessarily, and thus cause blow-outs below the dam, such as have occurred, the writer is informed, in some recent applications of the grouting method.

The result obtained by all the precautions at Hinckston Run was, not only a water-tight and practically indestructible dam, but the people in Johnstown were completely reassured, thus permitting the company to proceed with the construction of other large reservoirs in the same district.

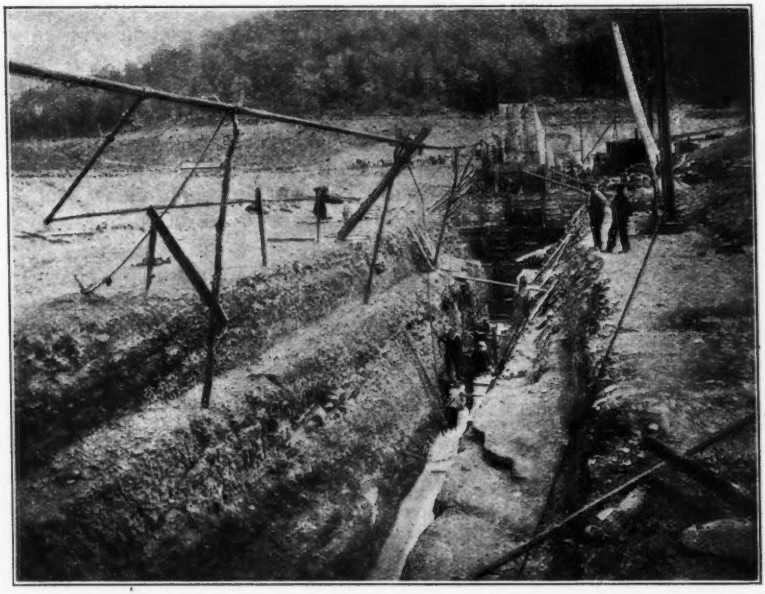


FIG. 33.—WESTERN SECTION OF CORE-WALL DITCH, HINCKSTON RUN DAM. PARTLY COMPLETED CORE-WALL, IN BACKGROUND, WITH VERTICAL BONDING GROOVES.

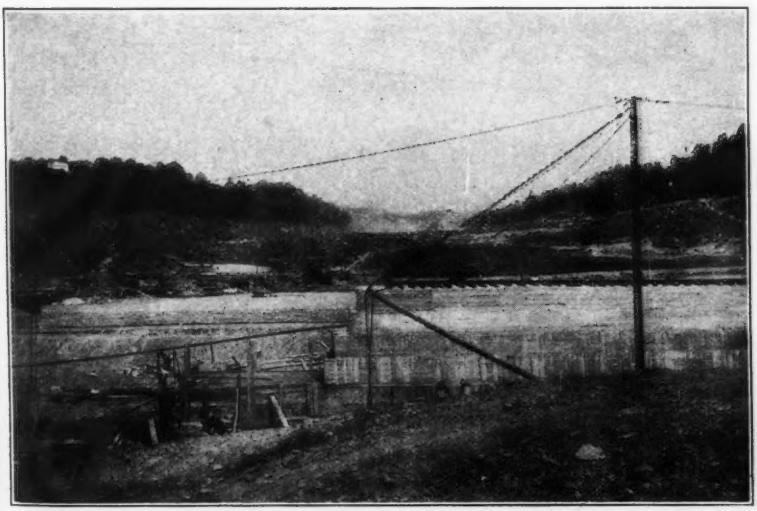

FIG. 34.—PARTLY COMPLETED CORE-WALL, HINCKSTON RUN DAM. LOOKING NORTH, TOWARD RESERVOIR.

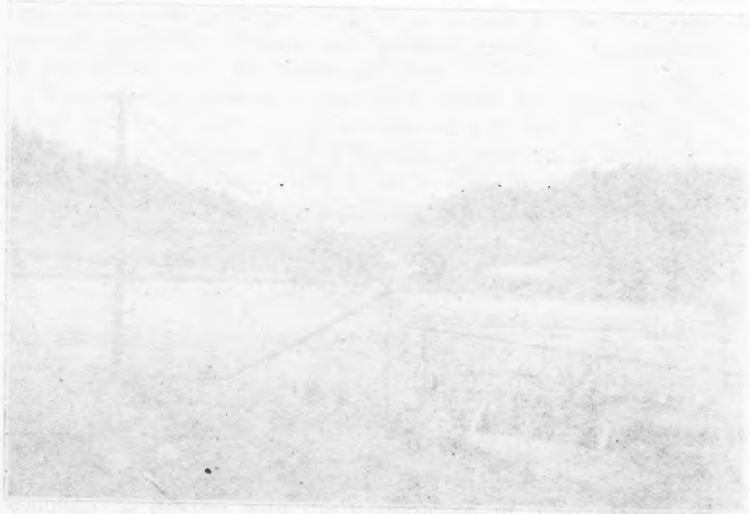

Mr. Souder.

The writer considers the grouting for the Hinckston Run Dam to have been successful. In any case, extraordinary care must be taken in applying it, and then only after conscientious study of conditions, and actual tests to determine its availability for the given locality and material. The apparent success of the grouting method for cutting off the underflow at Estacada and other places would indicate careful attention to these requirements.

The writer questions the advisability of using air pressure much in excess of 60 lb. in work of this class.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

PAINTING STRUCTURAL STEEL: THE PRESENT SITUATION.

Discussion.*

By A. H. Sabin, Assoc. M. Am. Soc. C. E.†

Mr. Sabin.

A. H. Sabin, Assoc. M. Am. Soc. C. E. (by letter).—It is not the desire of the writer to engage in unnecessary discussion, but it is desirable to correct misstatements of facts. Mr. Gardner questions the statements made as to the Havre de Grace Bridge tests. It is true that in the paper as first published the percentage of silicates, etc., in Paint No. 6 was too low, but a correction was made at the time of reading; the quantity of red lead was variously estimated at from 65 to 71% by different analysts. Paint No. 10, Mr. Gardner says, contained 10% of litharge, which was one analysis, but the same laboratory reported three other analyses of this paint showing 7.1, 6.8, and 8.5 per cent. Paint No. 11, he says, contained 5% of litharge; the four analyses give 3.51, 3.61, 2.99, and 4.14 per cent. The method used in the Contracts Laboratory‡ at that time gave results too low in red lead; the statement made by the writer was based on private information, and is probably accurate.

Mr. Gardner says:

"The only authoritative paint tests, to determine the efficiency of single pigments as preservers of iron and steel, which have ever been made, are those by the American Society for Testing Materials, at Atlantic City, N. J., in 1908."

If this is true, the writer should have mentioned it in the paper; it seems, therefore, incumbent on him to explain his views as to the matter. In the first place, he objects to the statement that these

*Continued from February, 1914, *Proceedings*.

† Author's closure.

‡ The analyses reported from the Contracts Laboratory may be found in *Proceedings*, Am. Soc. for Testing Materials, Vol. VIII, Plates I to III.

Mr. Sabin. tests were made by the American Society for Testing Materials. The plates were selected and cleaned, and the paints were designed, made, and applied by persons employed for the purpose by an association of manufacturers of mixed paints. The entire scheme and plan was theirs; and the only way in which that Society was mixed up in the matter was by accepting an invitation from the owners of the tests to inspect, by a committee, the prepared plates, as to the history of which they knew nothing except what the owners saw fit to tell them. According to Mr. Gardner, these tests show that no important single-pigment paint, and no simple mixture, such as can be made by an ordinary painter, gave results at all to be compared with the complex paints made by the people who designed the tests. Exception to this general statement may be taken in the case of a few pigments which are too costly to be used, especially the basic chromate of lead, which is described by Mr. Gardner as having "high litharge content", when in fact it contains no litharge at all.

The writer does not regard tests of this sort as authoritative or conclusive. He has before this been on a committee to inspect tests devised by Mr. Gardner, and has been impressed with the unfailing certainty with which they proved Mr. Gardner's contentions; and, for that reason, he can attach no value to them, however unprejudiced and competent may be the inspecting committee. This opinion is strengthened by the observations of A. W. Carpenter, M. Am. Soc. C. E., of the New York Central Railroad, and Mr. S. S. Voorhees of the Bureau of Standards.* Mr. Carpenter observed that in many cases three coats of paint on these panels were going to pieces in 20 months, though similar paints, according to his experience, would be better after an exposure two or three times as long, in New York City. Mr. Voorhees, who had been Chairman of the Committee on Protective Coatings from its beginning, said the Havre de Grace plates, after 5 years' exposure, were in better condition than those of the paint manufacturers' after 1½ years.

Mr. Toch's discussion contains two or three curious misstatements. He says that "every one of these red leads [on the Havre de Grace Bridge] was coated over with a carbon paint". According to the published analyses, as already referred to,† the pigments of Paints Nos. 10 and 11 showed only a trace of carbonaceous matter. He also says that his own paint was No. 12 and was the only one used in only two coats, all the others having three. The tables just referred to show complete analyses of each of three coats of paint on this section, the only one having but two being Section No. 1. It is reported‡ that:

---

* *Proceedings*, Am. Soc. for Testing Materials, Vol. X, p. 90.

† Also Plate IV, Vol. VIII, *Proceedings*, Am. Soc. for Testing Materials.

‡ *Loc. cit.*, Vol. XIII, p. 338.

"Three paints (Nos. 6, 10 and 11) in Class I, under each of the separate spreading rates, may each well be designated as excellent. * * * What differentiates these paints from all others under observation is the fact that while all the other paints except one furnish their best protection, such as it is, under the 600 sq-ft. rate of spreading and are generally markedly less effective under the thinner film rate, these three show such slight variation under different rates of application as to appear equally protective under either." Mr. Sabin.

This disposes of Mr. Toch's statement that the report "describes as excellent nine paints, three of which are red lead". Mr. Toch also says: "every paint chemist knows that there are some red leads that contain nearly 1% of caustic soda"; as a matter of fact, all red lead is made in a reverberatory furnace, and it is plainly impossible for caustic soda to be present in such a product; if any were there, it would be quickly changed to carbonate; no one has ever seen any.

Mr. A. S. Cushman deplores the fact that the paper "entirely ignores the electrolytic theory of the mechanism of the reactions which lead to metallic corrosion." It may be that this criticism is justified; but the writer's view is that a discussion of the theory more properly belongs in a meeting of chemists rather than engineers. The writer believes that he has read everything Mr. Cushman has written on the subject which he plainly regards as peculiarly his own. The writer's ignorance, therefore, is not due to lack of instruction, doctrine, or reproof, but probably consists in a pernicious tendency to try to check up theory with practice, which, however useful in practical work, is sometimes greatly disapproved by the theorist. What Mr. Cushman regards as the true theory of the corrosion of iron is, in the writer's opinion, that the action of water alone is all that is necessary for such corrosion to go on, and that the accidental presence of anything else is needless and not to be considered. This theory involves the supposition that in all water there is a portion which is ionized; that is, part of the hydrogen exists uncombined with the rest of the molecule, an unstable condition, which results in the formation of new compounds when another substance, as iron, is present. This theory, as regards the corrosion of iron, was first proposed by Mr. W. R. Whitney, now Director of the Chemical Laboratory of the General Electric Company, several years before Mr. Cushman adopted it.* Mr. J. N. Friend, who is Principal of a technical college in England, has been the chief opponent of this theory; he has been supported by grants from the Carnegie Institute, of Washington, and has contributed papers to the *Proceedings* of the Iron and Steel Institute on the subject, in which he believes that he has experimentally disproved the theory in question. A full discussion may be

**Journal*, Am. Chemical Soc., 1903, pp. 394-406, Whitney; and *Proceedings*, Am. Soc. for Testing Materials, 1907, pp. 211-228, Cushman.

Mr. Sabin. found in Mr. Friend's book.* Mr. Whitney, in his original paper, pointed out the enormously greater theoretical efficiency of carbonic acid, which is probably not denied by any one; and as this acid is a normal ingredient in air and rain, and all natural waters, it has always appeared to the writer that the pure-water theory of corrosion was of doubtful practical value. Further, in view of the fact that no one doubts the existence of electrical disturbances coincident with chemical action in general, and especially as it has long been known that electric instability is provocative of corrosion of iron, it seems to be an arrogant assumption to claim the exclusive application of the term electrolytic to the very limited theory propounded by Mr. Whitney, a restriction never proposed by him.

The fact that iron does not rust in certain solutions was known many years ago. Such facts are explained, some of them, and perhaps all may be, by the modern theories of chemical action; and Mr. Cushman has laudably attempted to apply such knowledge to the paint industry. The question in regard to this is: are his inventions, whether patented or not, of any practical value? The only answer the writer can give is that they do not appear to be. Mr. Cushman seems to believe that a linseed oil film absorbs water from the air, that it is in a sense hygroscopic, and that part of the solid particles of pigment in a dried paint film are really in solution; that this water, which is to all intents in solution in the solidified oil, acts on the iron and causes corrosion, and if some slightly soluble chromate, for example, is in the pigment, it will be in solution in this water and will prevent or forbid, or, as he says, "inhibit" corrosion. It is a very pretty theory, but does it work?

In reply to this, attention is again directed to the official report.† After 5 years' exposure, nineteen test panels, representing as many paints, were removed from the Havre de Grace Bridge, photographed, and then the paint was thoroughly cleaned off and the surface of the metal inspected for rusting. Excepting a few spots, where the coating was obviously injured accidentally, the surface of most of these plates was in exactly as good condition as when first painted. According to Mr. Cushman's theory, all these plates should have rusted under the paint; none of the paints used contained what he regards as efficient inhibitors, and some of them contained large quantities of carbon, apparently lampblack, which Mr. Cushman says is the worst stimulator there is. The paint in all cases was thin, being three coats at a spreading rate of 900 sq. ft. per gal., or a total thickness of 0.005 in., and had been exposed to the moist salt air from Delaware Bay, at the mouth of the Susquehanna River, for 5 years. The writer thinks this proves that a good paint, properly used, keeps out

* "Corrosion of Iron and Steel," 1911, pp. 44-67.

† *Proceedings*, Am. Soc. for Testing Materials, Vol. XI, pp. 175-180.

Mr. Sabin.

air and water; and, as long as it remains intact, it protects the metal; when it has deteriorated so much that it has holes through it, the air and water get to the iron, which begins to rust. As long as there are no holes, no inhibitor is needed; when there are holes, no inhibitor will do any good. No doubt there is a difference in the value of pigments; perhaps a soluble sulphate acts to some extent by conducting water through a film, and perhaps acts on the oil itself; perhaps a substance like carbonate of lime forms a soap with the oil and injures it in that way; but of more practical importance is the greater or less surface attraction between the pigments and the oil; in this respect the differences are great and characteristic. To illustrate this, let us remember that when one end of a small glass tube is put in water the water rises, as we say, by capillary action, in the tube; but, if mercury is substituted for water, the surface about the glass is depressed as though it were repelled. These are cases of surface tension and attraction. In an exactly similar way, some pigments have more or less surface attraction for oil. The most remarkable, and at the same time the most important, case is where, in the manufacture of white lead, the pigment is subjected to prolonged washing with pure water, then allowed to settle, and the wet pulp is agitated in a mixer with raw linseed oil. Although the oil is lighter than water, it displaces the water, mixes with the pigment, and forces out the water, which runs off the top, leaving the lead and oil almost free from moisture. Red lead may be treated in a somewhat similar manner, but of course it is not, as it is a furnace product. As far as the writer knows, no other pigment will act in this way; in most cases the presence of a little water in the pigment greatly obstructs its proper mixing with oil; but pigments differ greatly in this attraction for oil; which may partly account for the widely varying quantities of oil required by different pigments. To give an entirely different illustration: it is common knowledge among all paint makers and users that 1 quart of turpentine will thin a batch of paint as much as 2 quarts of linseed oil, because of the greater fluidity, or less viscosity, of the former. However, if we make a stiff paste with any ordinary pigment, as white lead, we require a certain quantity, say 8% of oil; if we substitute turpentine for half of this oil, it will take, not 2%, as might be thought, but 6 per cent. This remarkable fact leads to the consideration that the paste is a plastic body rather than a viscous one, and the function of the liquid is to stick the solid particles together, which the oil does much better than the turpentine, the surface attraction of which for the lead is very low; but, when more oil has been added, to make paint, which is a viscous but not a plastic body, turpentine is more efficient as a thinner than oil. In a similar way we account in part for the advantage of proper cleaning of steel before painting. It is well known that any ordinary oil easily

Mr. Sabin.

wets clean iron and steel, spreads over its surface, and is removed with difficulty; but, if the surface is fouled with anything which does not attract the oil, the latter when brushed out into a very thin film—and paint films are very thin—may break and leave holes, or pores, through which the atmospheric agencies get to the metal.

If, now, the pigment is one which has a great surface attraction for the oil, it is obvious that, when the paint is brushed out to a thin film, the presence of these solid particles in vast numbers will tend to hold the film together, to make it in fact tougher, so that it will be less likely to break into holes; and this is one reason why fineness is one of the most desirable qualities in a pigment; and why such a paint brushes out easily into a thin film, or, as we say, has good working quality. It is also a reason why a paint of good working quality (if it has no counterbalancing defects) is a good protective paint, for it makes a continuous film. Conversely, if the attraction between the pigment and the oil is slight, the paint is less likely to be satisfactory in any respect. Nor is this advantage likely to disappear when the film hardens; for the particles which attract the oil are likely to be more tightly cemented into the mass and form an element of strength rather than weakness; and if, in addition, the pigment is one which shows very little, or perhaps negative, attraction for water, it is likely to show great resistance to atmospheric action.

Linseed oil is an excellent insulator against the transmission of electric currents; and some pigments are themselves non-conductors, though others are the contrary. As it is generally agreed that electric tension is an effective cause of corrosion, it is desirable that paint for metal should contain pigments which will tend to insulate, rather than to break down the insulation given by the oil itself. This is a very different thing from Mr. Cushman's theory that certain pigments embedded in a cement of dried oil will act, in conjunction with pure water (which, in the writer's opinion, could not possibly get there), as a primary battery bringing the iron into solution. Mr. Cushman has elsewhere described the action of certain pigments as like a poison to iron; if correct, which in some cases at least may be doubted, it is because of their unfavorable relation to the oil, which renders them incapable of making good films, and the remedy should be looked for in this direction, rather than by his favorite prescription of a homeopathic dose of some inhibitor.

It is well known that some paints, including some varnish paints, and especially red lead in oil, adhere to iron and steel much better than others. Probably the mixture of a pigment in the vehicle affects its surface attraction to the metal. When we consider that often as much as one-third of the volume of a paint is composed of these solid particles, and that, in the case of a really fine pigment, there

Mr. Sabin.

are from 25 to 50 particles overlying one another in a film 0.002 in. in thickness (this supposes them to be 0.00001 in. in diameter, which is within the truth), it may be believed that the action of such a mixture is very different from that of oil alone.

Mr. Carpenter's discussion is interesting and valuable. In Table 1, showing his red lead experiments, it is notable that the quantity of paint used in the second series was 6.3% more than in the first (owing to the use of more pigment), but the surface covered was almost 30% more; and in three cases out of five the working quality of the paint was better, and equal in the other two. If a mixture of 30 lb. of red lead to 1 gal. of oil will work better and cover 28% more surface than a 24-lb. mixture, the fact is worth knowing, and should lead to considerable corrections in common practice.

The relative fineness in these tests was determined by the weight in grammes per cubic inch. The writer does not regard this as a safe method. Certainly, a very fine red lead, after being packed in a barrel in the usual way and then sifted to make it perfectly loose and open, will weigh several more grammes to the cubic inch than it did before being barreled; and it is probable that the volume depends as much on the friction between the particles as on anything, and this, again, may depend on their electrical condition, shape of particles (red lead particles differ in shape according to the material from which they are made, some of which is crystalline), and probably many other unknown causes. At all events, in the laboratory with which the writer is connected, the best-known volume apparatus gives results so widely and irregularly at variance with those of a more nearly absolute method which is checked by actual microscopic measurement, that it is not regarded by the writer as entitled to much consideration. It is possible that a fine red lead may contain considerable litharge, if it is taken out of the oxidizing furnace too soon; also, it is, at least theoretically, possible to oxidize highly a somewhat coarse material; but, in general, the finer the material the higher is the oxidation.

Mr. Carpenter's criticism of lack of definiteness as to the composition of the Havre de Grace tests has already been met by the figures given; attention is also asked to Mr. Wagner's discussion giving his experience with red lead ranging from 96.48 to 98.63% for 5 years, with satisfactory results. It should not be forgotten that, in the Havre de Grace tests, at least two of the red leads were what may fairly be called high grade, and were furnished by some of the largest and most experienced paint manufacturers in the country; and it is fair to infer that these makers desired to make the best possible record, and therefore that they had evidence, satisfactory to them, that this was the best material to use; as it proved to be.

Mr. Sabin.

As to why it should be better, the writer must admit that the reasons given in the paper are partly theoretical; but he does not see why he should be denied adopting a theory any more than other people, particularly as this one has nothing novel or original about it, is generally held by the trade, and has been forced on him by the constant experience of a quarter of a century. Age, however, does not make a theory right, any more than it does a man; but it entitles it to respectful consideration; it has successfully served a useful purpose for a long time. There is a broader ground, however, on which all can meet; for all agree that more than half the battle is in getting the paint applied to a clean surface in a smooth and uniform coating; smooth, because resistance to wear is much increased by the absence of ridges, lumps, and grains in the surface, and uniform, because thick masses of paint are waste, and thin places are weak. As Mr. Coombs puts it, a $5 man with a $1 paint is better than a $1 man with a $5 paint. Now the whole history of the improvement of red lead as a paint has been of this nature: to please the consumer, it has been made continually finer in texture, so as to be free from roughness and disposition to run, and lower in litharge, so as to be less active to oil and therefore more manageable. Tendency to settle is not so much a matter of specific gravity, but is caused by coarseness; no paint settles less than white zinc and white lead, which are very heavy but very fine; and no paint is more refractory in its general behavior than a low-grade, red-lead paint which has begun to get thick and viscid. It accords, then, with general experience, that a red lead which consists entirely of impalpably fine particles and has about the same relation to oil that white lead has, will be easily applied and form a smooth and uniform coat; and that, irrespective of the theoretical questions involved, it will practically be better on the average and last longer. This, it is submitted, is in accord with all experience with painting in general.

One more observation is suggested by Mr. Carpenter's discussion which is that it is difficult to determine spreading capacity in a panel test. The painter instinctively tries to spread all alike, so as to give each paint a fair chance; the more conscientious he is, the more his results may vary from what are actually secured in working under average conditions. It may be doubted whether a test of less than a barrel of paint is of much value in this regard.

In conclusion, the writer would explicitly deny the charge, made by Mr. Cushman and his associates of the paint manufacturers' organization, that he claims to have said the last word in respect to the protection of steel, and that there is no need of further investigation of paint problems. Such a charge will not be taken seriously by any member of the Society. Another assumption, that the paper was designed to create an interest in red lead, is really based on the fact that every one is interested in that substance, and when any one has

anything essentially new to say about it, whatever else he says is likely to be neglected. This very fact, that it is a widely known and valuable material, made it proper to mention, in a paper of this character, any important improvement in its manufacture or use, and the fact that the writer is able to speak authoritatively of its composition and character seemed a good reason for doing so. It is not a perfect paint; there is no paint suited for all uses; but that is no reason why we should not know as much as we can about any of them, particularly those which we use the most. Mr. Sabin.

DISCUSSION ON CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINERS.*

By Carl H. Fuller, Assoc. M. Am. Soc. C. E.

Mr. Fuller.

Carl H. Fuller, Assoc. M. Am. Soc. C. E. (by letter).—The writer has been vitally interested in the report and the chart of the Special Committee which has been investigating the matter of compensation of engineers and in the discussion of the subject following its publication. The work of the Committee is certainly thorough and commendable, and, should its efforts result in improving the standards of the average member of the Profession, it will merit the gratitude of every member of the Society as well as the Profession at large.

However, the writer cannot help but feel that the chart fails to represent actual average conditions, owing to several reasons, one of which is the effect of the maximum compensation line, containing several of what may be called abnormally big incomes. It will be conceded that the *Transactions* of this Society, owing to the extremely technical nature of a large portion of the papers, do not represent the ideas of the majority, who have neither the time nor the qualifications to prepare and discuss the subjects presented, but, represent the opinions and results of the labors of a very small minority, who being favored with ability and opportunity, derive pleasure in devoting their time to research and such work. Thus, in the consideration of this subject, it appears that the discussions represent the academic opinions of those whose successes in business, if platted as an income line on this chart, would rise above the average, rather than the opinions of the majority, whose income line would fall materially below this average.

The object of every professional organization is the betterment of its individual members, and the matter of personal income is bound

* Continued from April, 1914, *Proceedings*.

Mr. Fuller.

to have its reflex influence on the purely professional or technical aspects of that society. From the very nature of things, every paper presented before this Society reflects the financial success of the writer, and there are without a doubt a large number of members, who, if it were not for the handicap of family and the necessity of providing for them, would be glad to contribute very materially to the *Transactions* of the Society. Therefore, if the Society cannot give serious consideration to the material, individual condition of its membership, it will fail to represent the ideals of the majority; thus, the matter of personal or professional income becomes as much a matter of concern to the Society collectively as it does individually.

Out of curiosity, the writer platted his own income line for 15 years, superimposed it on the chart, and found that, being a very ragged line, it projected alternately above and sometimes very considerably below the average line on the chart, although a modified line of averages would follow the average on the chart quite closely. Nor does the writer believe that his success is materially different from that of the majority of engineers with whom he is acquainted, and the conclusion is reached from experience and observation that this Profession is one of constant change and vicissitude, as few engineering positions can reasonably be expected to be permanent. In no way can the Profession be compared with any other professions or industries, and the completion of a building, a railroad, or other project, naturally releases one or many engineers from an engagement that may perhaps reflect the greatest credit on their ability. Then again, the public in general has a very vague conception of an engineer's work, which, in a measure, is due to its transitory nature; consequently, many irregular employers of engineering services fail to appreciate the attainments of a man qualified to perform this kind of work and incidentally appraise his services at the valuation in dollars and cents that he himself places on them.

Architects, in their societies, have found it no disgrace to define their compensation, and physicians and those of other professional organizations have scheduled the value of their services in varying degrees; therefore, why should not this Society endeavor to establish a higher standard, which will command the respect of other men. There is no doubt that the compensation for engineers is less than that for men in other lines of industry, and as the public very largely measures a man's success and ability by the amount of compensation he is able to demand for his services, it behooves the Society and the Profession to protect its professional honor by demanding for its members fees which are consistent with the services rendered.

Conservation and scientific management have become quite a fetish in the Engineering Profession, yet, as a whole, it is more extravagant and wasteful of its energies than any other body of intelligent labor

in the world. If this statement is challenged, one item alone will be considered: The average engineering job (not position) lasts from 3 to 18 months, occasionally longer. In the transition from one job to another the average engineer will lose at least a month, and, if his last project has been finished late in the year, he is likely to lose 3 or 4 months. Without resorting to statistics, the writer thinks it may safely be assumed that the average engineer loses on this account fully one-tenth of his time and income, through no fault of his. If this waste can be eliminated—for waste it is—not only will the average income line on the chart be raised, but a very material difference will be made in the minimum line, for this waste naturally applies to those whose incomes fall in the lower half of the chart, and among whom there are many able men. Is not this waste as worthy an object of conservation for the Society to consider as that of the water-powers and forests? Mr. Fuller.

Some one has remarked that a capable engineer will always have a job, but this statement needs to be examined. Is it the man who is capable from an engineering standpoint, or the man who is a good salesman of his services that gets the job? The writer is inclined to think that it is the latter; for, getting a job requires salesmanship of the highest degree, more so than selling rails or cement. Consider the men who maintain large offices successfully. Without any discredit to them, let it be asked how much work they get because of their engineering ability, and how much they get from salesmanship? The latter often brings the larger fees. The writer knows an engineer, whose name has been connected with monumental work all over the United States, who cannot perform the simplest equations, yet, from his sales ability and knowledge of men, he has a large practice. If the writer should mention his name he would be accused of slander. Therefore the statement that, if a man has ability he will always have a job, is fallacious.

From these thoughts arise two ideas: (*a*) Can the Society as a body wield an influence that will tend to increase the compensation of its members and the Profession at large so that it will be consistent with services rendered? (*b*) Can it do anything to prevent the loss of time of its members? The writer thinks it can, and, furthermore, that it is one of the obligations of its existence, because no other body of men is qualified to do this.

There are many phases to this proposition. It is the biggest problem that has ever been presented to the Society. Is the Society going to table it, after some academic discussion, or is it going to seek a remedy? The writer would suggest that a standing committee be appointed to continue the work that has been started.

As to the conservation of the time lost, the Society can, if it will, afford immediate and effective results by the establishment of

Mr. Fuller.

a secretaryship or bureau, under the direction of a competent engineer who knows the work and the men, the duties of which will be to furnish a clearing house for the services of its members. In this the employing member will receive as much benefit as he who is seeking employment, for the reason that a properly conducted department of this kind will try to place the right man in the right place, instead of "bleeding" an unemployed man who can ill afford it. The writer is of the opinion that every member who has used the employment agency to secure help has been disappointed in the results obtained, because the employment agent is only looking for his commission. In one instance an agent offered to divide his commission if the writer would employ his clients and discharge them again when the fee had been paid.

Some member on whom fortune has smiled, in the way of successful positions, may object that it lowers the dignity of the Society to go into the employment agency business; but, who has a greater right to conserve the time and compensation of its membership than this honorable body. Each and every member belongs to this Society for one of two reasons: either to derive some benefit from the organization or to confer some good on his fellow-members. Therefore, while the Society is caring for the intellectual welfare of its members, why not go a step farther, and provide for their material welfare, thereby permitting them to derive greater intellectual benefit. The writer hopes that there will be further discussion on this subject from the majority of the membership whose income falls below the average line, in order that some light may be obtained on the whys and wherefores.

STORAGE TO BE PROVIDED IN IMPOUNDING RESERVOIRS FOR MUNICIPAL WATER SUPPLY.

Discussion.*

BY MESSRS. E. P. GOODRICH AND JAMES L. TIGHE.

Mr. Goodrich.

E. P. GOODRICH, M. AM. SOC. C. E. (by letter).—What Mr. Hazen has done in the design of probability paper is unique, and, with easily obtainable information as to the meaning of lines drawn on it in relation to probability formulas, his new device should be of almost as much value to engineers as the well-known logarithmic paper.

The writer believes that the work Mr. Hazen has done in applying the theory of probabilities to the data on annual stream flow and required storage, is a material advance in engineering science. Mr. Hazen has shown conclusively, in the writer's opinion, that the methods of computation to be followed in utilizing the theories of probability are applicable to water problems. The next step in the solution must be what is normally called that of inverse probability or the breaking up of the probability curve found from actual data in any case (such as that prepared by Mr. Hazen and shown in Fig. 29) into several possible component probability curves. This work is exactly comparable with the analysis which is now so common with reference to tidal and similar observations, which have been found to follow compound harmonic relations, breaking up this combination curve into the several simple harmonic ones which, when recombined, will produce the actual result observed in Nature. In the case of the harmonic curves, the tracing back of the several simple harmonic functions to their causes has been found relatively simple. It is similarly to be expected that, if Mr. Hazen's combination probability curve can be analyzed into two or more simple normal probability curves, in combination with one or more other simpler curves, the causes operating

* Continued from March, 1914, *Proceedings*.

Mr. Goodrich.

to produce the latter can be discovered, and further refinements can be worked out in the engineering of water-works design.

Several explanations of the skew curve, which Mr. Hazen found with regard to run-off data, are possible. One such explanation, which seems to the writer more than possible is that a normal probability variation is superposed upon a condition which would produce a periodic variation of long range. Evidently, if the data happened to have been secured for years which range near the minimum of a periodic fluctuation, the exact conditions, with reference to the data found by Mr. Hazen, would be reproduced. In the paper Mr. Hazen makes reference to such periodic variations in rainfall and run-off, and it is the writer's idea that the skew nature of the curve found by him indicates, primarily, that the data do not cover a large enough range of years to be entirely conclusive in the deductions which can be drawn. In the meantime Mr. Hazen's work will represent the acme to date.

Mr. Tighe.

JAMES L. TIGHE, M. AM. SOC. C. E. (by letter).—The ingenious and unique methods of analysis followed in the production of this remarkable paper, and the conclusions and results therein set forth, must be of the greatest interest to all hydraulic engineers.

In the earlier days of providing domestic water supplies from catchment areas, little attention was given to the relation between run-off and storage, with the result, naturally, that deficiencies generally occurred in the drier years. After a time these deficiencies led to the establishment of empirical rules or formulas for storage based on low rainfalls, or, where run-off records were available, to the tentative and laborious methods of tabulation.

It was not until the early Eighties that W. Rippl, Docent at the Royal Technical High School at Gratz (Styria), made public his graphical method for the calculation of storage known as the mass-curve method. As originally given, this method was followed in such calculations until the report on the water supply of New York by John R. Freeman, M. Am. Soc. C. E., was published in 1900. In this report a more convenient mass-curve method was shown, in which a single curve served for all rates of draft, whereas, in the original Rippl method, a new curve had to be made for each rate.

In this mass-curve method and in the other methods for calculating storage, it was generally sought to calculate from the rainfall or stream-flow records of the particular catchment area in question, or, if these were not available, from the rainfall or stream-flow records of some other catchment area applicable, the storage required to maintain certain drafts through the driest period covered by the records, and little if any attention was given to other important phases of the question, outside of evaporation, until the presentation of Mr. Hazen's paper.

Mr. Tighe.

In this exhaustive analysis, some new ideas relative to storage, which were never brought into the question before, have been treated at great length. Of these, the amplification of the dry years and their recurrences, the normal storage diagram, and the coefficient of variation may be mentioned. For the latter, hydraulics is under great obligations to the author, inasmuch as it must be admitted that, up to the present time, the science gave no yardstick whatever by which the variation in stream flow could be determined.

The coefficient of variation proposed is an ingenious one, and will not only serve the purpose for which it is used in the paper, that is, for storage calculation, but will enable a comparison to be made of the variation of streams, not only in one section or territory, but all over the world.

As the variation of a stream, however, is influenced, among other things, by the area of its catchment, inasmuch as the greater this area, the less variation the stream is likely to have, perhaps the author at some future time could expand this idea to cover the catchment area. This might not be included in terms of the coefficient, but possibly in some other way so that when comparing two or any number of streams, relative to variation, their catchment areas would be brought into the comparison.

In regard to the normal storage diagram developed, this, if the writer understands it correctly, is not based on the actual records of the flow of any one particular stream, but on an artificial record formed from the records of the flow of all the streams used in the analysis. Such an artificial record makes a series covering a period of 300 years, or thereabouts, and may be open to the objection suggested by the author, that it does not reflect any climatic changes which might occur in the actual series, were it not for the fact that such changes or movements are on such a large scale of time that any objection of this kind may be disregarded.

The utility of the normal storage diagram is shown by the fact that by this method the storage required on any stream, to maintain a certain draft, can be determined more accurately than from the actual run-off records of the stream itself, unless perhaps these records covered an exceedingly long term of years, many times longer than the longest now in existence. This diagram method is a great advancement in storage calculation, and very likely will be used as the standard method in such calculations in the future. Even were it the case that actual run-off records could be depended on for storage calculation, this normal storage diagram would be valuable as a check.

A very important point stated by the author is that the storage on a tributary, within certain limits is as useful as that on the main stream. This no doubt is true within the limits stated in respect to reasonably large storage, but is it true in respect to small storage

Mr. Tighe.

where the capacity of the reservoir and the draft thereon would be such that the reservoir would empty and fill several times a year or several times in the summer season? For instance, if the capacity of the Borden Brook Reservoir, of the City of Springfield, referred to by Mr. Hazen, was only 70 000 000 gal., would this reservoir, with its 8 sq. miles of catchment, be as efficient as the intake reservoir of the same capacity with its 48 sq. miles of catchment, assuming that the pipe line had a discharging capacity of 20 000 000 gal. per day?

The writer has made no test figures on this, yet it seems to him that the intake reservoir would be the more efficient, as it would be possible for it to fill more often in the summer season, because of its larger catchment, than the Borden Brook Reservoir.

Another point that should not be overlooked, relative to storage on tributaries, is the water that is lost by percolation and evaporation in its course from the storage to the main stream and intake, especially if conveyed intermittently in the old stream bed.

Although considerable attention has been given to the loss of water by evaporation from the surface of reservoirs, it seems that much less has been given to the loss of water by percolation from reservoirs.

When a reservoir is built and filled, the level of the ground-water above the dam is raised and, consequently, some extra storage capacity is provided beyond the apparent capacity of the reservoir, especially if the ground surrounding the reservoir is porous.

On the other hand, because of the ground-water being raised above the dam, if there is any connection between this and the ground-water below the dam, the flow of the latter, owing to the higher head, must be increased, and this increase will come or be fed from the reservoir. It can be argued, of course, that, with the foundations of a dam resting in impermeable material, percolation from the reservoir, under the dam at least, might be considered negligible. The writer would like to get the views of the author and of others on this matter, as he thinks that the loss of water from the average reservoir through percolation is more of a factor than is supposed. If this is the case, it seems that, in storage calculation, especially as other phases of the question are being so closely analyzed, percolation should also be considered.

In conclusion, the writer, under whose supervision the daily flow of the Manhan River, furnished the author, was measured, and who naturally has been interested in and has given some attention to the matter of stream flow and storage, considers this paper the most comprehensive analysis that has ever been presented on the subject. The author certainly deserves the thanks of all hydraulic engineers for the exhaustive manner in which he has treated the subject and the new light which he has thrown on it, especially those phases of it which hitherto have been neglected.

AN INVESTIGATION OF SAND-CLAY MIXTURES FOR ROAD SURFACING.

Discussion.*

By James Owen, M. Am. Soc. C. E.

James Owen, M. Am. Soc. C. E.—This question of sand-clay roads was initiated about 10 years ago at the suggestion of the United States Office of Public Roads, and the writer believes that roads of that type were afterward constructed in South Carolina. The idea was suggested to the writer by his experience in the construction of a speedway, for the surface of which no natural materials were available, so that they had to be manufactured in the best possible manner, and the mixture that had been made in South Carolina was tried. There was available some very good, greasy, gray clay, which was essential for the work, and about 2 miles away there was a very good bed of sand to mix with it. The writer, however, made five or six mixtures of the sand and clay before he obtained what might be considered a perfectly consolidated surface. These mixtures were put down in places where there was considerable travel, and thus the best method of surfacing was ascertained. Mr. Owen.

The speedway was built with the mixture giving the best results; the clay was spread over it in lumps; the sand was then put on top of that, and the two were spaded together and rolled.

One interesting thing happened in these experiments. The mixture was made according to a preconceived idea of the standard surface, and when it was completed it was impossible to get a smooth trotting way for horses. The surface was rolled, but it would not come down, under the conditions prevailing at that time. By accident, a bed of what is known as New Jersey loam was found, and a coating of this, from ¼ to ½ in. thick, was put on, rolled down, and,

* Continued from April, 1914, *Proceedings*.

Mr. Owen.

with the consolidation of the gravel and the clay on top, and the addition of the loam, a perfectly smooth and constant roadway surface was obtained.

It is well to note here that, in the construction of sand-clay roads, strange results may be obtained. In New Jersey there are two classifications of roads; in the north they are of stone, in the south, gravel. In both sections there is an enormous amount of travel, automobile and horse, and the experience of to-day tends to confirm the belief that the gravel roads are much more constant in uniform maintenance, much cheaper to repair, and much more satisfactory to travel on than the stone roads, and here comes in the whole question, as enunciated in this paper, that the original idea of macadam roads as the best means of travel under the old regime, of horse travel and hard steel tire travel, has passed away; that in all localities of the United States there is material at hand which should be used for the purpose for which it is required, and manipulated so that the results are good.

Roadmakers in the future must not rely on stone roads to maintain the desired conditions for the wear and tear of travel.

In the case of the Georgia roads, the climate must be considered, and this may be more serious than is thought at first. There the frost does not penetrate to any great depth; there is rarely any frost, except in the high lands; but that does not affect the maintenance of roads, and, as far as that is concerned, the practice that is applicable to Georgia may not be applicable in the Northern States, where frost often penetrates the ground from 2 to 3 ft.

Experience to-day in New Jersey, however, shows that there is no doubt that it is much more economical to use the natural material, properly manipulated, than to import ideal material to make the ideal road, which in the end does not give ideal results.

CINDER CONCRETE FLOORS.

Discussion.*

By Messrs. Arthur H. Diamant and J. R. Worcester.

Mr. Diamant.

Arthur H. Diamant, Assoc. M. Am. Soc. C. E. (by letter).—The writer has read this paper with great interest, and, having had experience during the past 5 years in the use of reinforced cinder concrete, agrees with the author that the present method of tests of floor slabs does not conform to conditions on construction work.

Aside from the design, however, the great fault in the construction of such floors is the lax supervision in placing the material. The majority of apartment and loft buildings in New York City are erected by speculators. The men in charge of the erection of these structures for the builders know very little about reinforced concrete work, and are rarely on the floors where the arches are being placed. The inspector of the Building Department has so much work to supervise, that he can devote very little time to this part of his duties, and the result is that there is too much dependence on the contractor to do good work. His men, usually unskilled laborers, are required to fill a certain number of centers in a specified time, and, in order to do this, sufficient care is not taken to place the reinforcing metal properly. With the exception of wire-cloth, the spacing of the metal is usually guessed at, and thus its weight per square foot of arch is often insufficient.

Another cause of trouble is in the mixture of the cinder concrete. When hand mixing is done, there is very little attempt to measure the ingredients, and, in machine mixing, the cement, sand, and cinder hoppers are not kept filled. The writer was on the tenth floor of a hotel, being erected under his supervision, when he noticed that the cinder

*This discussion (of the paper by Guy B. Waite, M. Am. Soc. C. E., published in April, 1914, *Proceedings*, and presented at the meeting of May 6th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Diamant. concrete which was being hoisted did not seem to have the proper proportion of cement. The contractor had an efficient mixer plant in the cellar, and when the cause of the poor mix was investigated, it was found that the laborers were so busy keeping the sand and cinder bins filled that they neglected the cement bin.

One of the most pernicious faults is the cutting of holes in concrete arches shortly after they are laid. In an inspection of a large loft building, the writer condemned a panel of reinforced cinder concrete floor which adjoined a stair-well. A large hole had been cut through this panel for a 5-in. soil pipe, and smaller holes for the passage of water, steam, and electric pipes. The reinforcing rods had been cut and bent so that they would not interfere with the pipes. Before the arch could be taken down, it failed because a barrel of lime was rolled over it. There is no excuse for work of that kind, for, in a properly designed structure, the location of all pipe lines is known, and openings can be left in the arches when they are poured.

In conclusion, the writer wishes to state once more that, even though the floor slab is well designed, the careful work of the engineer is not properly carried out because of inefficient supervision in the field.

Mr. Worcester. J. R. Worcester, M. Am. Soc. C. E. (by letter).—The argument of the author in favor of establishing allowable unit stresses and physical properties of cinder concrete as a means of calculating safe loads for certain designs is sound and convincing. Though there are some difficulties in the way of reaching satisfactory units, they should be overcome if we consider that the margin of inaccuracy will be much less than in any attempt to determine strength by crude, isolated, field tests of actual construction.

The chief uncertainty with regard to the material is on account of the wide range in quality of cinders, running, as they do, all the way from a soft, impalpable ash to a vitrified clinker. The writer has not seen a satisfactory specification for cinders, by which good material for concrete can be distinguished from bad. It is easy enough to write one which will exclude bad material, but the trouble with it would be that it would be so stringent that no material could be obtained which would comply with it. It is to be hoped that further light will be shed on this subject. Another uncertainty in the value of the best cinders lies in the great irregularity in the proportion of fine particles, corresponding to sand, which is contained in every load. This variation is so great in practice that frequently a batch of concrete may contain scarcely any material which could be classed as coarse aggregate. Under such circumstances we would obtain for a product, using 2 parts of sand and 5 of cinders, a 1:7 mortar, of which part of the aggregate is less hard than sand. It is chiefly to these peculiarities that we may attribute the wide discrepancies in the results of experi-

ments with cinder concrete, as shown in Table 3, and the general disrepute which the material has among structural engineers. Mr. Worcester.

It is true that cinder concrete slabs, in spite of their disadvantages, have been used to a phenomenal extent, and it is also a fact that failures which can be shown to be due to the use of this material are remarkably few in number. This being the case, it certainly behooves the Profession to deal with the subject in a tolerant spirit, and to do what it can to lay down rules for its safe use.

This Society's Special Committee on Concrete and Reinforced Concrete, in its report presented in 1913 prescribed units, which, though tentative, seem to correspond fairly well with present practice. The subject of the modulus of elasticity of cinder concrete is not referred to in that report, presumably being classed with concretes having an ultimate strength of less than 2 200 lb. per sq. in., for which the ratio of moduli is to be taken as 15. This low value of the ratio does not correspond with general practice. With this exception, the rules laid down in the report cover the method of computation and manipulation quite comprehensively.

Although cinder concrete may prove entirely satisfactory in floor and roof slabs, it is altogether too uncertain a material to recommend for beams, girders, and other structural members, and it is objectionable even for slabs when the span is too great. The reason for this seems to be that the softness of the aggregate allows an inelastic set, which becomes apparent in the deflection when the span is sufficient. It may not be possible to make a hard and fast rule limiting the length of span, for in some places the deflection may not be of importance, or, it might be compensated by cambering the slabs, but the peculiarity should not be lost sight of.

REINFORCED CONCRETE RESERVOIR AND COAGULATION PLANT AT ST. LOUIS, MO.

Discussion.*

By Edward Flad, M. Am. Soc. C. E.†

Mr. Flad.

Edward Flad, M. Am. Soc. C. E. (by letter).—Mr. Finch suggests that the working tensile strength allowed for the concrete, 290 lb. per sq. in., is excessive. He is correct in his statement that Mr. Andrews advises the use of this stress for 1:1:2 concrete. The writer is unable to state definitely at this date the line of reasoning that led to the selection of 290 lb. as a safe stress. Probably the original intention was to use 1:1:2 concrete, allowing the stress recommended by Mr. Andrews, and, later, when it was decided to use a 1:1½:3 mixture, it was concluded that the stress of 290 lb. would be well within the probable ultimate strength of that concrete; moreover an additional factor of safety was provided in assuming a high value for the modulus of elasticity of the concrete. In the structure as built no vertical cracks have been observed, but there is still evidence of moisture at some of the horizontal joints, due probably to a failure to clean the old surface properly before depositing the new concrete.

The construction suggested by Mr. Finch and Mr. Potter for the joint between the side and bottom of the tank appeals to the writer as an improvement, except for the difficulty of making this joint watertight. In the design of the St. Louis Reservoir, the stresses at this point could only be determined approximately, there being a combination of cantilever action and hoop tension, and, in this respect also, because of the extra expense involved, the design is inferior to one containing an expansion joint at the junction of the side with the bottom.

* Continued from March, 1914, *Proceedings*.
† Author's closure.

Mr. Flad.

The arrangement for the removal of sludge while in operation, suggested by Mr. Potter, would have been of doubtful benefit for this particular reservoir, as there are two preliminary steel settling tanks, each 75 ft. in diameter and 25 ft. high, through which the water passes and from which the greater quantity of the sludge is removed before the water enters the concrete reservoir; there is no difficulty about arranging for cleaning the reservoir at times when it will not interfere with the operation of the plant, and the proportion of water to sludge required in cleaning is probably less than would be required with the plan of removal during continuous operation.

It is gratifying to note that Mr. Buerger's interesting comparison of designs containing cantilever walls with those providing for tension rings leads to the conclusion that the design selected, to wit, the tension-ring type, was practically justified, his theoretical determination of economical diameter for the reservoir in question being 134 ft., whereas the actual diameter is 150 ft. As Mr. Buerger surmises, the nature of the foundation available was really the controlling feature in deciding between the two types of reservoirs. A uniform distribution of the load was considered to be of paramount importance.

Mr. Buel seems to be in error in stating that, according to the formula given for the thickness of the concrete wall, the ratio of stress in the steel to stress in the concrete is 9 to 1. The formula is supposed to provide a ratio of 10 to 1, and is derived as follows:

Designating quantities and dimensions by the letters used in the paper:

Area of concrete per vertical foot of wall $+ 12\ T - A$,

Hoop tension $= pr = A\ s + (12\ T - A)c$,

$$pr = A\ s + 12\ Tc - A\ c,$$

$$T = \frac{pr - A\ (s - c)}{12\ c},$$

Assuming that $s = 10c$,

$$T = \frac{pr - 9\ Ac}{12\ c},$$

which is the formula given in the paper.

The description by Mr. Wegmann of the construction and failure of the Stony River Dam emphasizes again the desirability of carrying cut-off walls down to rock or impervious strata. Happily, the failure was not as serious as at first reported, but it furnished a tender morsel for those who, through personal interest, were unfriendly to the Ambursen Company.

THE POSSIBILITIES IN BRIDGE CONSTRUCTION BY THE USE OF HIGH-ALLOY STEELS.

Discussion.*

By Messrs. M. J. Butler, Albert Lucius, Henry W. Hodge, Charles Evan Fowler, L. J. Le Conte, N. Petinot, Leon S. Moisseiff, and F. W. Skinner.

Mr. Butler.

M. J. Butler, M. Am. Soc. C. E. (by letter).—The author has once more placed the members of the Society under obligations. He has dealt most ably with a matter of great interest and importance.

It is an error to assume that the limit has been reached with ordinary carbon steel—undoubtedly, if the customer is willing to pay the price, the steel maker will supply a much better quality of steel:

(*a*) By fluid compression of the ingots;
(*b*) By careful heat treatment and lighter and slower blooming, putting more work on the bloom;
(*c*) Cropping away all segregated, piped, and inferior metal;
(*d*) Careful re-heating of billets, slower rolling, and better work generally on the rolls and sections;
(*e*) Such a quality of acid steels—possibly with a cheaper alloy than nickel—would allow of higher unit stress in large members, where shock and impact would be amply cared for.

Alloy steel of nickel and other materials may be secured to meet any reasonable requirements. Steel makers will rise to the occasion, when the demand justifies the outlay in getting ready for steel of such a quality.

In very great bridges, such as are under consideration in this paper, the increased price of the metal would not be so serious; there are too

*This discussion (of the paper by J. A. L. Waddell, M. Am. Soc. C. E., published in March, 1914, *Proceedings* and presented at the meeting of April 15th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Butler. many other factors that go to make the cost, such as the substructure, the erection of great cantilevers, and the special tools, plant, and shop, to fabricate the member. The engineering and the financial costs are to a considerable extent independent.

Mr. Lucius. ALBERT LUCIUS, M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest. Its objects are stated to be: First, to give the weights of different span lengths for simple spans and cantilever bridges, using metals of various elastic limits; secondly, to indicate the extreme practical limits of span lengths of cantilever bridges constructed of such metals; and, thirdly, to demonstrate the comparative economics of finished bridges involved in using metals of the various assumed elastic limits.

Concerning the weights of long-span bridges built of assumed metals of higher elastic limits, whatever their actual amount may be, there is little doubt that weights would reduce about as formulated in the paper if the unit stresses follow the elastic limits, as they should, provided the metals have the same superior properties as to ductility which they have as to strength, for then only would confidence in the material be justified to the extent of developing all sections and all details carrying calculated stress by the proportional unit strains. Members and their connections and all details, the function of which is to distribute local strains over sectional areas, could then be made of the same material working under the same stress and elastic condition, but, if the high alloys are of inferior ductility and connections and distributing details must be made of softer and weaker metals, and the unit amounts of extension and compression vary in the different parts forming the ends of a member, the difficulties of making proper connections would be increased and the advantages of reduced main sections would be partly neutralized.

Concerning the extreme length of cantilever spans, it is the writer's opinion that it has been reached, as far as practicable; that it will not be carried very much further, even if higher grade material is available; and that every consideration of reliability to carry load, simplicity of the carrying member, availability of the highest grade of material, and ease of construction and erection, points to the suspension bridge as the type to take care of extreme span lengths where bridges are preferred to subway constructions.

Concerning the economics involved in the use of high elastic limit materials, these are expressed most readily in a sufficiently satisfactory way by the ratio of elastic limit stress to price per pound of the metal, and whichever metal sells at the least price for the highest elastic limit, all other properties being in proper relation to it, is the cheaper material, and this would apply to the various types of bridges alike as far as their fabricated cost is concerned. Generally,

the idea of using simple spans up to their extreme limit of possible application cannot be attractive to engineers, because there is hardly any other reason for long spans than the requirement to maintain an unobstructed right of way under these proposed spans. The feasibility and cost of erection will determine the type, and a cantilever or continuous span over several openings, or an arch bridge, all of which can be erected cantilever fashion, would probably be selected before the economic limit of the fabricated simple-span bridge is reached. Besides, in long-span bridges, especially where prominently placed, esthetic considerations do and should enter more emphatically and obscure the importance of relative economics still further. Mr. Lucius.

Concerning the desirability of improving on the present available bridge material, both as to uniformity of present properties and in regard to increase of all its elastic properties and its ductility, there is probably no difference of opinion among engineers, and each, no doubt, does all he can to encourage and help push manufacturers to favorable solutions; but this is another subject, and in the care of the metallurgist. It is hardly likely that it is inertia alone which makes progress slow and apparently does no more than maintain a stationary level. It is more likely that there is a greater possibility of making economic improvements on the present grade of steel by cheapening it and making it more uniform in quality, than to make a higher grade of steel at a price which will give it an advantage commercially, except for special purposes, in which case the price is not so important relatively to the whole special purpose to be accomplished. The vast majority of railroad bridges can be well taken care of with the present grade of steel, and whether lighter sections of higher grade steel worked to higher strains would be an all-round improvement for the bulk of bridgework, might be open to debate. It certainly would not be the case, in the writer's judgment, if higher strength did not also carry with it higher ductility.

The engineer must get next to the metallurgist. It is highly probable that any metallurgist who knows how to produce a better steel alloy at commercial value will succeed very promptly in getting it on the market, and engineers would accept it as promptly and adjust their constructions to it.

HENRY W. HODGE, M. AM. SOC. C. E.—The length of bridge spans in general use has been increasing steadily, and we have reached limits where the dead weight of the structure has become the largest portion of its carrying capacity, so that some method of keeping the weight down is a necessity for the construction of the great spans now contemplated. The only way to reduce the dead load materially is by the use of metal of higher carrying capacity than our present materials, and a long step in this direction has been made by the use of nickel Mr. Hodge.

Mr. Hodge. steel, which has 50% greater carrying capacity than the carbon steel in general use.

The trusses of the three 668-ft. spans of the St. Louis Bridge were designed for nickel steel throughout, except certain minor sub-members. Nickel-steel eye-bars and carbon-steel compression members were also used, the floor system and bracing being of carbon steel in each case.

The weights of each span were:

With complete nickel-steel trusses..... 9 200 000 lb.
With nickel-steel bars, and the rest of carbon steel .....10 900 000 lb.

The dead load of railways, tracks, etc., was 5 500 lb. per lin. ft., so that the total average dead load was:

With nickel-steel trusses.....19 300 lb. per lin. ft.
With nickel-steel bars, and the rest of carbon steel .....21 800 lb. per lin. ft.

Thus, the nickel-steel compression members in the trusses made a difference in weight of 2 500 lb. per lin. ft., or 13 per cent.

The average live load on the two decks was equal to 16 600 lb. per lin. ft., thus the use of nickel-steel compression members made a saving of 7% in the total load on the structure.

The average unit prices for the two classes of material in this structure, erected in place, were:

Nickel steel, 5.6 cents per lb.
Carbon steel, 3.95 " " "

making a difference of 1.65 cents, or 42% of the price of the carbon steel; but the elastic limit required for the nickel steel was 50% higher than for the carbon steel, so that the nickel steel was the cheaper, strength for strength.

This steel had 3¼% of nickel, but manufacturers are now commercially producing an alloy steel, with not more than 1½% of nickel, together with small percentages of chromium and vanadium, which has all the properties of this steel, at a very much reduced price, so that there is at present a readily obtainable material, which is 50% stronger than the carbon steel in general use, at a comparatively small increase in cost.

This increase of elastic limit to 50 000 or 60 000 lb. per sq. in. will help greatly in the construction of spans of considerable length; but, for the very long spans now being planned, a still stronger material is needed, and can economically be used at a very considerable increase in price. In the design for the 2 880-ft. suspension span for the North River Bridge at New York, there is great economy in placing the stiffening trusses along the cables, so that articulated

joints are required, thus necessitating eye-bars in place of wire, which has heretofore been used in long suspension bridges. Mr. Hodge.

The total live load on the eight tracks, two roadways, and two sidewalks, is 20 000 lb. per. lin. ft., when all are completely loaded; and, if the structure were made of carbon steel, the dead load would be about 110 000 lb. per lin. ft., which would make the sections almost prohibitive. The designs, therefore, have been based on the use of eye-bar cables of alloy, heat-treated steel, having an elastic limit of not less than 120 000 lb. Such steel has already been manufactured for limited sizes, and as it is only here required for eye-bars, from which any number of full-sized specimens can be tested to destruction, there will be no doubt as to whether the strength and other qualifications are fulfilled. With such material, the total average dead load of the structure is 64 000 lb. per. lin. ft., so that this material makes a saving of 46 000 lb. per lin. ft., or practically 50% of the total load on the structure.

Such a material will naturally cost a considerable price, but it will be about four times as strong as the usual carbon steel; and even at much more than four times the cost, it would make a saving, on account of the large decrease in dead load.

About 40 000 tons of such bars will be required, practically all duplicates, so that there is little doubt that they will be furnished at a price which will make a great economy in the structure.

The speaker, therefore, fully agrees with Mr. Waddell that such high-value alloy steels are a necessity for coming bridge structures, and has the fullest confidence that our metallurgists will meet the demands as they arise.

CHARLES EVAN FOWLER, M. AM. SOC. C. E. (by letter).—For many years the writer has known of the higher grades of steel produced by European manufacturers, but, owing to the great demand on the mills of the United States, it has been a case of taking what is offered by the manufacturers or paying the extras asked for nickel steel or anything except the ordinary grades. The tariff conditions will now allow the importation of European high-grade steels for Pacific Coast fabrication, but, until shops of sufficient size are established there, little advantage can be taken of such foreign products. This possible source of supply may eventually result in American mills being willing to meet the demand for nickel or other high steel alloys at a reasonable price. Mr. Fowler.

In the writer's discussion* of Mr. Waddell's former paper, "Nickel Steel for Bridges", he called attention to the possible use of ferruginous nickel as a cheap means of obtaining the nickel ingredient for nickel steel, and it is gratifying to know that this has been declared possible

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 300.

Mr. Fowler.

by competent metallurgists and at a reasonable cost; so that now it seems to be only necessary to find philanthropic steel manufacturers who will make only a reasonable charge for manufacturing plates and shapes of the desired composition.

To conduct the extensive experiments which are desirable on nickel steel and other high steel alloys, it will certainly be necessary to enlist a really enthusiastic support from the mills before anything satisfactory can be accomplished. When it is possible to do this, and to raise the necessary funds, the work should be carried out under the direction of this Society, acting in conjunction with the American Society for Testing Materials.

The great amount of work done by Mr. Waddell, as shown by this and his former paper, will entitle him to a large share of the credit for the great spans which may be built in the future if, as a consequence, higher steels are made possible.

The diagrams of weights of metal in bridges, for both the usual and the higher grades of metal, show conclusively what one would naturally infer as to the great saving that may be made by the use of a steel of high elastic limit which can be obtained at a reasonable cost. It is to be regretted that all such investigations are not made on a common basis, both as to loadings and specifications, so that the work of various engineers along similar lines may be more readily compared, and the desired end be more quickly reached. To this end, the proper committee of the Society should formulate rules for all such investigations and calculations.

The engineer who has been in direct touch, not only with structures manufactured from his own designs, but also with those of hundreds of other engineers, as has been true in the writer's case at the shops of the Youngstown Bridge Company and at other large shops, and throughout a wide experience of more than a quarter of a century, will realize that the personal equation of the designer does result in such a wide variation in weights that, unless each one is tied down to the hard and fast rules of the same specifications, the resulting data cannot readily be compared, especially for long spans.

The real comparison can only come from the various designs that would naturally be made for any specific location and the investigation of the composition of the necessary high-grade metal required for that particular structure, as was the case for the St. Louis Eads Bridge. A structure costing from $30 000 000 to $60 000 000 would easily stand the charge of $100 000 or more for such experiments.

Long spans are seldom contemplated or built from motives of economy, but are the result of the necessities of commerce, of finding good foundations, or as necessary connecting links in lines of traffic and communication, regardless of whether the structure in itself will

Mr. Fowler.

be a paying investment. When, from some cause or other, long spans are found to be necessary, the engineer must determine the class of structure that will be possible:

First.—To carry the class and quantity of traffic to be imposed or cared for;

Second.—That will be possible, due to the foundations that can be obtained;

Third.—That will be possible, due to the material that can be obtained from which to fabricate it;

Fourth.—That will be possible, owing to the limitations that may be imposed by the methods and means of construction;

Fifth.—That will be a paying investment from a dividend-paying standpoint, if that be necessary;

Sixth.—That will at least be possible from related financial conditions.

These factors are correlated to such an extent that a very wide investigation would be necessary, in order to set the limits of span and expenditure.

Recent researches seem to indicate:

That simple spans can be constructed by using nickel steel to a greater or less degree, up to lengths of from two to three times those which have been built;

That suspension spans and cantilevers will reach about the same cost at some span length between 1 600 and 1 800 ft.;

That, by the use of nickel steel to a large extent, suspension spans can be built economically, where the traffic is sufficient, up to about 3 000 ft. span;

That, by the use of nickel steel to a large extent, cantilevers can be built economically, where the traffic is sufficient, up to about 2 500 ft. span.

However, inasmuch as the dead weight of such structures is very great in proportion to the live load, we can largely disregard impact, and use correspondingly high unit stresses, thus allowing at present cost the use of nickel steel for all the suspended structural parts of a suspension span, thereby making such a structure, with its high steel cables and comparatively low erection cost, the best to adopt for long spans, from every point of view, beyond a span length of about 1 700 ft. Such a structure will carry satisfactorily all classes of traffic, and satisfy most fully all the six requirements previously given.

The question of right of way and terminals may add so greatly to the cost of the project as to make its realization impossible.

In his discussion of Mr. Waddell's former paper, the writer called attention to the various cost factors that would come in to determine

Mr. Fowler.

the possible span length of any type, or indeed the type to be used in a particular location. The sub-factors of erection cost will also serve to decide these things. The empirical erection cost formula, devised by the writer some years ago, will serve to illustrate this point, there being six different factors which enter into the cost of only this one portion of the amount necessary to expend for the construction of a bridge superstructure:

$$C = a + \sqrt{l} + \frac{3}{4}h + \frac{200}{d} + 5p - \frac{1}{5}\sqrt{w - 500}$$

C = cost of erection, in cents per 100 lb.;
a = a constant for each type of structure;
= 15 cents for railway pin trusses;
= 25 cents for railway riveted trusses;
= 20 cents for railway girders;
= 20 cents for highway pin trusses;
= 30 cents for highway riveted trusses;
= 15 cents for highway girders;
l = span length, in feet;
h = height of falsework, in feet;
d = daytime temperature, average, in degrees Fahrenheit.

Taking the case of a riveted railway span 225 ft. long, 48 ft. height of falsework, average temperature, 40°, 2 coats of paint, and weighing 2 100 lb. per lin. ft., we find the probable erection cost to be 83 cents per 100 lb., or $16.60 per ton.

A railway pin span of 144 ft., 36 ft. height of falsework, average temperature, 50°, 2 coats of paint, and weighing 1 400 lb. per lin. ft., erection cost equals 62 cents per 100 lb., or $12.40 per ton.

These two examples show what an influence a change in any one of the factors will have on the unit erection cost. For cantilevers of the type of the Poughkeepsie Bridge, or the Knoxville Bridge, designed and built by the writer (Fig. 24), every other span being a fixed or anchor span, the bridge must have falsework, so that, for a bridge of this type one can take the coefficient of h at only $\frac{3}{8}$ instead of $\frac{3}{4}$. The formula was deduced to fit certain conditions, which to a large extent were due to the personal equations of the designer and the erector; and, with plans prepared by some designers, the cost of erection would exceed very greatly the values found from the formula, it being only too common on the part of many designers to forget that structures must be erected at a reasonable cost, and still others seem to forget the process of erection entirely.

Many erection costs, of course, will exceed greatly what they should, due to unforeseen causes. The White Pass, Alaska, Arch constructed

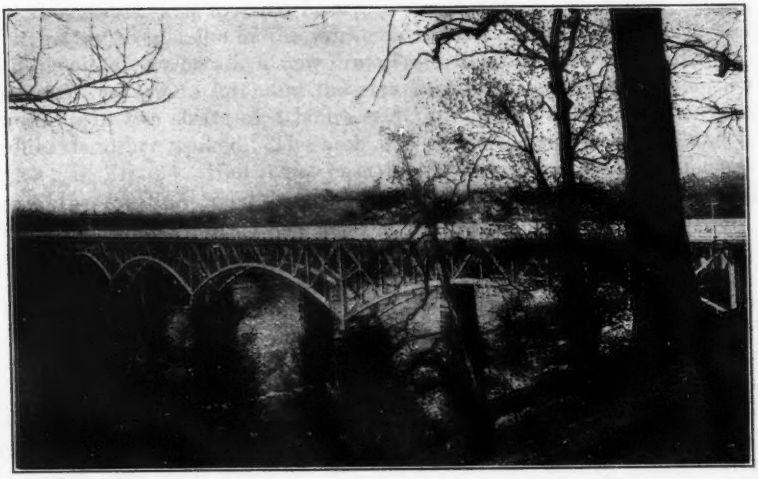

FIG. 24.—KNOXVILLE STEEL ARCHED CANTILEVER BRIDGE.

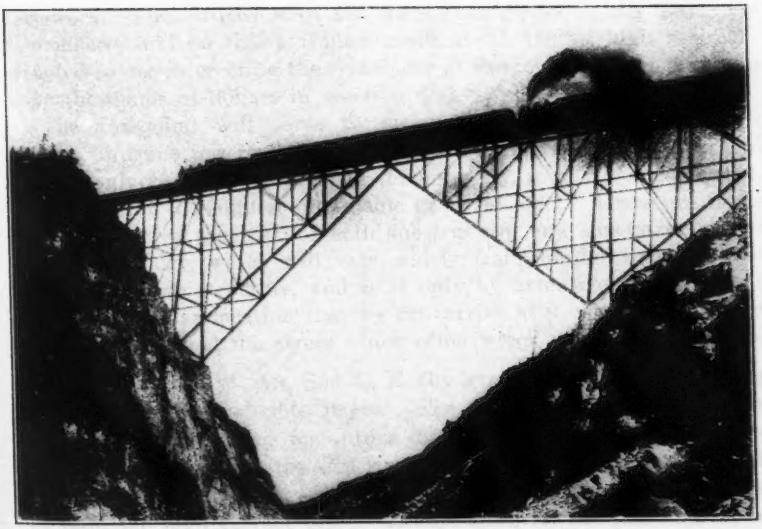

FIG. 25.—SWITCHBACK ARCH. WHITE PASS AND YUKON RAILWAY, ALASKA.

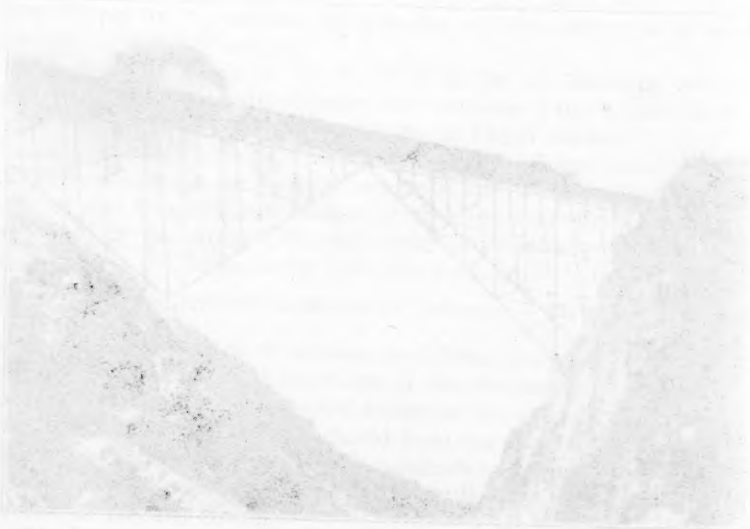

by the writer, was to have been completed before the winter season, but, owing to a strike of the workmen in September, and no telegraph line available to obtain a new crew from Seattle, 1 000 miles distant, some 6 weeks were lost, and the structure was completed by the men working in two shifts of 2 hours each, one crew warming up in camp while the other worked. The arch was completed in December, and is shown in Fig. 25. Had it not been for the delay and consequent extra cost, the erection could have been carried out on a very economical basis, as the falsework necessary for the anchor arms was very slight, and one top traveler carried out the entire work of erection. Mr. Fowler.

The extra cost due to delay in this or other cases, cannot, of course, be considered in making a design, but there are many features of erection methods which should be studied out during the original investigations. So far as the writer is aware, no scheme of erection was ever formulated for the construction of the Williamsburgh Bridge over the East River, on which he was Consulting Engineer for the erection of Manhattan tower and approaches. The Brooklyn tower erection had been planned and partly carried out by constructing trusses across from masonry pier to masonry pier, and these supported a temporary combination tower about 300 ft. high from which to erect the steel tower.

For the Manhattan end the tower was erected up to the floor level by stiff-leg derricks on a heavy bent at the end of the approach-span falsework. The latticed strut and floor-beam girder in the tower was also placed, and on this a timber tower about 150 ft. high was constructed to use in erecting the remainder of the tower steel, thus saving some thousands of dollars in erection cost.

The foregoing will serve to make perfectly plain the writer's reasons, in some few respects, for regarding diagrammed weights and costs as only very general proof of the necessity, in any particular case, for the use of the highest obtainable grade of steel. There are items in every part of the cost, of both substructure and superstructure of any great bridge, which will vary widely from similar items of cost in another large structure, and it is only by extensive investigations at each particular location that we can arrive at a close semblance of the truth and avoid the errors which often wreck meritorious projects.

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—The writer is highly pleased with this valuable paper. The practical results given are exceedingly encouraging for future developments. The writer would respectfully suggest to the experimenters that they also try a small batch of aluminum steel. The main objection to its use, heretofore, has been the high market price. Lately, however, the price has come down to 20 cents per lb. in large lots. It is his firm belief that if the ordinary steel is first "thoroughly purified", and its elastic limit, Mr. Le Conte.

Mr. Le Conte. thereby, raised to 60 000 lb. per sq. in., and then a cake of aluminum, say 3%, be added to the molten metal, the result will be a highly satisfactory alloy, and at no great increase in cost per pound. The aluminum not only strengthens the steel enormously, but also toughens it and wipes out all brittleness, and thus renders all general shop work much easier and more satisfactory and reliable in every way.

In case some of the material should be condemned as not coming up to the requirements of the specifications, the condemned material could easily be turned over to the wire works which would be only too glad to get it, as this aluminum steel makes the finest kind of high-grade wire, suitable in every respect for suspension bridges, as it is exceedingly strong, tough, free from brittleness, and non-corrosive to a high degree. Ordinary sections of this alloy will have an elastic limit of 100 000 lb. per sq. in., and the wire possibly 200 000 lb. per sq. in.; and at a cost probably not exceeding that of ordinary carbon steel by more than 2.5 cents per lb.

Mr. Petinot. N. PETINOT,* ESQ.—The speaker agrees with Mr. Waddell that the first step is to experiment on the purification of steel so that the metal may be brought to its maximum efficiency. He cannot see why it should not be possible to secure regularly physical properties within a limit of 5% in a steel carrying predetermined quantities of carbon and nickel, for instance.

The speaker has been experimenting extensively, both in France and in the United States, with the manufacture of alloy steels, and particularly with nickel steels of the same supposed analysis, and has found that very often two melts of open-hearth nickel steel of the same analysis, when physically tested, have shown a variation of 15% or more. Carrying the investigation further he found, by microscopic examination, a large difference between the two steels. The poorer very often showed very large colonies of manganese sulphides, iron silicates, and slag. These are weakening elements in steel of any grade, even if it is an alloy of plain carbon metal.

When the manufacturers of steel find the way to remove such elements, it will be possible to secure the maximum physical qualities from each component of every grade of steel, and there should be no great difference between any two steels of the same chemical composition.

Increasing the carbon content in steel of any grade is a cheap way to increase the alternate strength, and, according to the speaker's experience, a satisfactory way, provided the steel has been thoroughly cleaned and the segregation reduced to the minimum.

In reference to the possibility of producing a nickel steel by the use of a ferro-nickel containing 10% of nickel, this problem presents

* Metallurgist, The Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.

Mr. Petinot.

no difficulties at all, as such steels have already been produced in 5-ton melts. A few years ago a pig iron was produced by smelting pyrrhotite—containing nickel—in an electric furnace. This pig iron contained from 4 to 5% of nickel and was low in sulphur and phosphorus. By varying the proportions of such pig iron in the mixture used in making nickel steel by the open-hearth process, it will be possible to obtain any nickel content actually desired.

It will be noticed that, in the making of nickel steel, the nickel is usually added with the cold charge, and does not, therefore, oxidize during the periods of melting and finishing the steel, and its use as a component of pig iron would be the same under similar conditions.

The speaker believes that, by experimenting thoroughly with ferro-nickel in the manufacture of nickel steel, it will be possible to get a product which will be identical with that obtained by the use of metallic nickel, and at a much lower cost.

Mr. Waddell has asked what effect the use of titanium might be expected to have on the steel. Titanium has a great affinity for nitrogen and oxygen, so much so that, prior to this time, it has been very difficult to obtain a steel with a content of more than 0.25 of that metal, and such steel showed no particular advantages over one which had been treated with 0.10 of titanium, and after such treatment carried only 0.02 to 0.03 of the latter.

Titanium is on the market commercially in the form of ferro carbon-titanium, containing from 15 to 20% of titanium and from 6 to 8% of carbon. It has been found that a ferro-titanium, with a higher titanium content, has too high a melting point for general use.

Titanium, because of its affinity for nitrogen and oxygen, the latter either in the form of a gas or an oxide, is to be considered as a powerful deoxidizer and scavenger. It is the only deoxidizer known at present which can be used without danger of leaving any of the products of its oxidation in the bath of steel.

In the treatment of steel with titanium, the ferro carbon-titanium is always used as the last addition to the steel after it has been tapped into the ladle, that is, after manganese, silicon, or other alloys, if any, have been added. Titanium will react first on nitrogen (always present in a greater or less quantity), forming titanium nitrides (Ti_2N_2), which rise to the top of the ladle. It will then act on the oxygen in solution in the steel, and on oxides of iron, manganese, etc.

Particular attention is called to the presence of manganese oxide in steel. Ferro-manganese is added to the steel, not only as a deoxidizer, but also to furnish sufficient manganese to combine with the sulphur, giving manganese sulphides, which are less brittle than iron sulphides. It has always been found that the rolling properties of steel are enhanced by a small manganese content, and it is a well-known fact

Mr. Petinot.

that it is impossible to roll a steel ingot which does not contain manganese.

Now consider, for instance, what happens when manganese is added to molten steel. The iron oxides, for instance, are robbed of their oxygen, and manganese oxides are formed, as shown by the following chemical equation:

$$FeO + Mn = Fe + MnO,$$

but, as manganese oxide will partly remain in the steel, if a piece of this steel is analyzed, the chemical laboratory will report so much manganese, but there will be nothing to show in what form this manganese occurs, whether as an oxide, sulphide, or some other compound.

It is difficult to determine whether a remainder of manganese oxide in the steel is more or less harmful than a content of iron oxide, which it may have replaced. In the manufacture of soft steel, with a carbon content of from 0.08 to 0.10 and manganese content of 0.40, it has been proved that, by eliminating the manganese oxide completely, no blisters will be found when such steel is rolled into sheets and galvanized.

When titanium is added to steel it will react as shown by the following equations:

On nitrogen:

$$Ti_2 + N_2 = Ti_2N_2 \quad \ldots\ldots (1)$$

On oxygen:

$$Ti + O_2 = TiO_2 \quad \ldots\ldots (2)$$

On iron oxide:

$$2FeO + Ti = 2Fe + TiO_2 \quad \ldots\ldots (3)$$

On manganese oxide:

$$2MnO + Ti = 2Mn + TiO_2 \quad \ldots\ldots (4)$$

The titanic oxide (TiO_2) formed by any of the last three reactions will flux all particles of slag invariably suspended in the steel and carry such slag to the top of the ladle, which will enable steelmakers to teem into the ingots a product, practically free from nitrogen oxides and slag, which are the weakening elements in steel of every grade.

Another function of titanium is to reduce segregation to its minimum. The following explains briefly how segregation is produced: Steel must be considered as a mixture of pure iron, iron carbide, manganese sulphides, iron silicides, iron phosphides, etc., each of the components having different specific gravities, and varying melting points. Now, consider what will happen when an ingot mould is filled with molten steel: The wall of the mould will act as a chill, and the component having the highest melting point will be the first to solidify. If drillings are taken, starting from the outside of the ingot toward its center, it will be found that the carbon and other elements of lower specific gravity and higher melting points will be

higher inside the part cross-hatched in Fig. 26 and also at the top of the ingot. Mr. Petinot.

Now, consider why the various elements composing the steel will segregate, and why the maximum segregation will be found at the top of the ingot. This segregation is produced by the presence of oxides in the steel, no matter whether they are of manganese, of iron, or other elements. Take, for instance, a molecule of oxide, *R* (Fig. 26). The carbon of the steel will react on this molecule, giving carbon monoxide, according to the following equations:

(In the case of iron)

$$FeO + C = Fe + CO \quad \ldots\ldots(5)$$

(In the case of manganese)

$$MnO + C = Mn + CO \quad \ldots\ldots(6)$$

The tendency of this carbon monoxide gas is to release itself from the steel by rising to the top of the mould. The bulk of this gas has been produced in that part of the ingot which is last to solidify, as previously mentioned. This part of the ingot is composed primarily of iron carbides, iron phosphides, manganese sulphides, etc., so that all these elements will be found in excess near the top.

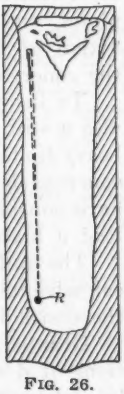

FIG. 26.

It very often happens that a steel which shows in a ladle test 0.40 carbon will show, when rolled into bars, a variation of carbon between 0.35 and 0.45. If titanium is added, it will prevent, to a great extent, the formation of CO in the moulds, because, as already shown by Equations 3 and 4, the titanium will react on these oxides in the ladle, so that, when the steel is poured into the moulds, the only segregation that will occur is that caused by the chilling action of the moulds.

The speaker's experience has been that a clean product, with very little segregation, can be obtained by the use of titanium, at an additional cost of from 25 to 50 cents per ton of steel treated, and, if this is so, the uniform composition of such a steel will easily warrant small additional expenditure.

LEON S. MOISSEIFF, M. AM. SOC. C. E.—This paper is most interesting and also most timely. It attempts to find a way to meet the ever increasing demands made on the ingenuity of the engineer and the resources of the capitalist by heavier loads and greater spans. There is no doubt that the author points the right way into the future: there is a need of a material of a higher strength than that of the steel generally used in bridge building to-day. Whether it be nickel steel, as recently used in some of our long-span bridges, or another kind of an alloy steel, still better meeting the requirements of bridge building, there is a technical need of a higher strength steel. Not only would Mr. Moisseiff.

Mr. Moisseiff.

heavy railroad bridges with their increasing freight loads be benefited by the higher steel, but also highway bridges of the longer spans.

The advent of heavy automobile trucks has made it imperative to provide heavy floors for bridge roadways. The old rule, of an inch depth of plank for every foot of span for the usual timber floor, died quite some time ago. Nowadays, concentrations of 10 000 to 15 000 lb. have to be taken care of on city highways. Even the old reliable buckle-plate, built in a suspended position, appears to have lost its good behavior. Recently, it has been found on some highway bridges that the buckle-plates are not sufficiently rigid, and that the pavement fails in consequence. This can readily be explained. The suspended buckle-plates are stiffened by the filling of concrete placed on them. The stiffness thus provided was sufficient for the old-time concentrations from wheel loads, and the pavement was supported rigidly enough to give good results. The increased concentrations of modern traffic, however, overcome the stiffening resistance of the concrete and the buckle-plates, and the curve of the plate is distorted under the advancing action of the load. This results in the crushing and crumbling of the concrete in the trough, and the ultimate failure of the pavement.

To insure the good behavior of a pavement, not only a strong but also a stiff support is necessary. Such support will be furnished by a heavy timber floor with floor stringers at close intervals, or by reinforced concrete slabs. In either case a floor system will be required which will have considerable weight. To take care of this additional weight and load a high-strength steel is wanted.

The author has gone to a great deal of trouble to show the economical advantage of higher steel, and there can remain no doubt as to the desirability of its use for bridges.

Granted, then, the desirability of the higher strength steel, questions of design may well be considered. One of these questions may be: what will be the effect of the higher steel on the stiffness and stresses of bridges built of that material?

The higher elastic limit of the new steel will be utilized, of course, for allowing higher unit stresses, which is the purpose of its use. The coefficient of elasticity being practically constant for kindred steel, the higher unit stresses will result in greater elongations of the individual members and greater deflections of the entire structure. The increased deformation of the trusses means a greater deviation from the original truss-form, and will result in much increased secondary stresses.

Assuming, as the author has apparently in the paper, that the allowable unit stresses will retain the same proportion to their corresponding elastic limits as they have in the present practice in the case of carbon steel, the allowable stresses for the hoped for high-alloy steel of 100 000 lb. elastic limit will be nearly three times those of carbon steel with its elastic limit of 35 000 lb. Evidently, the moving load deflections will

become considerable and the secondary stresses may attain the rank of primary stresses. How, then, to take care of the secondary stresses in the erection of the bridge, and provide for the deformation of the trusses under moving load, will raise new and serious problems in bridge design. Mr. Moisseiff.

Another question is how to connect efficiently the high steel members, apart from using pin connections. With common soft steel rivets the splices would be of excessive length, the efficiency of which is subject to much doubt. Consequently, high-steel rivets must be used. Nickel steel members have been designed by the speaker for corresponding nickel steel rivets, but these rivets have not always proved very satisfactory. They are not easily well driven and are difficult to remove. This refers especially to field rivets which have to be driven with a gun or a machine of limited pressure. Now, if nickel steel rivets having an elastic limit of 50 000 lb. present some difficulties, what will rivets of, say, 80 000 lb. elastic limit offer?

F. W. Skinner, M. Am. Soc. C. E.—The speaker, having recently had an opportunity of seeing some phenomenally large carbon steel rivets, made for the new Quebec Bridge, would like to confirm to some extent the views of the author and of Mr. Hodge. Some of these rivets—those for the cantilever arms—were 7 in. or more in length, with a diameter of 1¼ in. Mr. Skinner.

Some experimental work was done in which these rivets were specially designed with a slight taper at the points. They were quenched at the points in cold water. When driven, they were held in place by a pneumatic bucker, and the driving was done with a pneumatic hammer. The pneumatic bucker was a special tool, having a hollow cylinder in which a hammer was arranged. The hammer and cylinder were controlled independently, which enabled the bucker to be held in position, and then when the ordinary hammer was operated on the point of the rivet, the secondary hammer in the bucker was operated, and the rivet was thus driven simultaneously from both ends. The result was that they were exceedingly well driven. A row of rivets was driven partly by yoke machines and partly by the hammer and bucker process, as in the field. When they were cut in two, it was almost impossible to distinguish between them, the field-driven rivets being, for every practical purpose, as good as those driven by machine in the shop. Therefore, it seems quite reasonable to expect that field-driven rivets can be made substantially as good as shop rivets, and, if nickel steel rivets can be driven satisfactorily, it may go a long way toward producing equally good results in the field.

Regarding the possibilities of high alloy steel in bridges, there can be no doubt that the need of it is great and the prospect is alluring. The speaker supposes that it is generally agreed that there is difficulty

Mr. Skinner.

in securing uniformity in its production. A great many years were required to produce carbon steel which was trustworthy and uniform, and it will no doubt take as long to get alloy steel in uniform condition. The speaker would be very glad to hear from the author about the possibilities of developing a super-strong alloy steel by subjecting finished members to heavy test loads at the shops. It has been pretty well demonstrated that both the elastic limit and ultimate strength of carbon steel, for both tension and compression, can be thus greatly raised. The speaker does not know that this has gone farther than a demonstration, but it was considered more or less seriously for the Quebec Bridge, and perhaps for the St. Louis Municipal Bridge. Such treatment should achieve the double result of increasing the elastic limit and ultimate strength, and therefore the working capacity, and should serve as a valuable test or proof load, disclosing all serious defects.

If an increase of from 20 to 40%—possibly even more—can be practically attained at moderate expense for carbon steel, what would be the result if applied to nickel or other alloy steel? It may be inferred that important results can be obtained. The speaker thinks that it opens up a wide field of conjecture.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

GEORGE ALFRED NELSON, M. Am. Soc. C. E.*

DIED JUNE 3D, 1913.

George Alfred Nelson, the son of George and Abigail Marion Bigelow Nelson, was born in Lincoln, Mass., on September 20th, 1852. He attended the Lexington District schools and the Lincoln High School and was graduated from the latter in 1872. In 1873, he entered the Massachusetts Institute of Technology from which he was graduated in Civil Engineering in 1877. During a summer vacation, from June to September, 1875, he served as Rodman on the survey and construction of the Boston, Concord and Montreal Railroad, and as an Assistant in the office of the City Engineer, at Concord, N. H.

After his graduation from the Massachusetts Institute of Technology, Mr. Nelson spent two years at his home in Lincoln, and was engaged in surveying and various engineering works in that vicinity. In 1879, he went to Lawrence, Mass., where he was employed as sketch maker in the Designing Department of the Pacific Mills. He remained in this position until August, 1883, when he resigned to become Assistant Engineer in the office of the City Engineer at Lowell, Mass., which position he held until his death.

As Assistant Engineer, Mr. Nelson had charge of the design and construction of several bridges in Lowell, one of which was the Taylor Stone Arch Bridge across the Concord River, the location of which involved difficult foundations, and its successful completion showed the thought and skill devoted to its design. He also had charge of a complete survey of the city for assessors' maps; of all water-works improvements; the extension of the sewerage system into new territory; and the design and cost estimates for the abolition of grade crossings within the city limits.

Mr. Nelson was a man of strong character and his personality and keen mind impressed all with whom he came in contact. He had never been very strong physically, and his constant and close attention to the details of his work affected his health so that he was forced to seek rest at frequent intervals. His death occurred on June 3d, 1913, after an illness of a few months. Mr. Nelson had never married. He is survived by a sister and two brothers.

He had always shown much cleverness with his pencil and crayon, and was an expert photographer. He had shown his photographs at

* Memoir prepared by the Secretary from material on file at the Society House.

various exhibitions in the United States, receiving many medals for his artistic work. With a few others, he was selected to represent the United States at an international exhibition at Berlin, Germany, where his photographs won for him a silver medal.

Mr. Nelson was an active member of the Eliot Congregational Church Society, at Lowell, and for many years was President of the John Eliot Literary Society, contributing greatly to the success of its work by his active energy and personality. He was a member of the Alumni Association of the Massachusetts Institute of Technology, the Technology Club of the Merrimac Valley, of which he was an active president for several years, and the Association of the Class of 1877 of the Massachusetts Institute of Technology. He was also a member of the Boston Society of Civil Engineers, having designed the pin which was adopted by that Society. He was devoted to outdoor sports and took an active part in the snowshoe trips of the Appalachian Mountain Club, of which he was a member. He was also a member of the Vesper Country Club, at Lowell, and an expert golfer.

George Alfred Nelson was elected a Member of the American Society of Civil Engineers on April 4th, 1911.

BENJAMIN FRANKLIN MORSE, M. Am. Soc. C. E.*

DIED FEBRUARY 17TH, 1914.

Benjamin Franklin Morse was born on June 7th, 1829, in South Kirtland, Geauga County, now Lake County, Ohio, and in 1836 became a resident of Painesville, in the same county. During his residence at Painesville, he attended the common schools and afterward the Painesville Academy; later, he studied mathematics and civil engineering with General E. A. Paine, a graduate of West Point, who had retired from the United States Army.

Mr. Morse was identified with much of the pioneer railroad building in Northern Ohio, in the capacity of Assistant Engineer, in which connection he represented the Lake Shore Railroad, aiding in the construction of the line between Cleveland and Erie, Pa., in 1851 and 1852.

In 1853, he was Assistant Engineer, under Major Potter, at the harbors of Fairport, Ashtabula, and Conneaut, Ohio. During the season of 1854 he was First Assistant, under Captain Howard Stansbury, U. S. Engineer, in the examination of the harbors on Lake Erie west of Cleveland, namely Lorain, Vermilion, Huron, Sandusky, and Monroe, Mich.

* Memoir prepared by J. F. Morse, Esq.

As First Assistant Engineer, Mr. Morse had charge of a line from Tiffin, Ohio, to Fort Wayne, Ind., now a part of the Nickel Plate System. During 1855 he was Assistant Engineer in charge of a survey for The Cleveland and Mahoning Railroad, from Youngstown, Ohio, to New Castle, Pa., and from 1857 until 1862, he was First Assistant, under Mr. Charles Collins, in the Engineering Department of the Lake Shore Railroad, between Cleveland and Erie, Pa.

In 1862 the four railroad companies, the Cleveland and Columbus, the Cleveland, Painesville, and Ashtabula, the Cleveland and Toledo, and the Cleveland and Pittsburg, proposed through their Presidents to build the present Union Station in Cleveland. The Presidents constituted the Building Committee, with Mr. Amasa Stone, of the Lake Shore, as Chairman, and he appointed Mr. Morse as his Engineer. The latter drew the plans for the station, and they were approved by Mr. Stone. They included what was probably at that time one of the largest train-sheds in the United States. Mr. Morse superintended the building of the Union Station, completing the work in 1865.

In 1868, as Chief Engineer, he surveyed the line from Chardon to Youngstown, Ohio, which is now a branch of the Baltimore and Ohio Railroad, extending from Fairport to Youngstown. As Chief Engineer, he also made a preliminary survey for a railroad from Cleveland to Sharon, Pa.

Mr. Morse afterward became interested in the erection of many of the public buildings in Cleveland and superintended their construction. He superintended the construction of the City Work House and drew plans and superintended the rebuilding of the Newburg State Hospital, which was destroyed by fire in 1872.

In April, 1875, Mr. Morse was appointed City Engineer of Cleveland, in which capacity he served for 9 years. He remodeled the plans and completed the Superior Street Viaduct, which was opened in 1878. While acting as City Engineer, he estimated and reported on several high-level bridges, and one of the plans he advocated, the Central Viaduct, was adopted and developed.

He also first suggested and planned for the intercepting sewer for the City of Cleveland. He was appointed by the Building Committee to superintend the construction of the Society for Savings Building, but before active work was begun, he engaged with the Lake Shore and Michigan Southern Railroad Company to look after the building and rebuilding of its stations at Toledo and Chicago.

In 1890, under the new Building Code, Mr. Morse was appointed Building Inspector, and served in that capacity for 3½ years. After retiring from this office he spent some time in travel, and laid aside active business except for occasional consultation work in engineering lines.

On September 19th, 1913, Mr. Morse was seriously injured in an automobile accident, from the effects of which he died on February 17th, 1914, at the Battle Creek Sanitarium where he had gone for treatment.

In 1855, Mr. Morse was united in marriage to Matilda Craft, of Tiffin, Ohio. He is survived by three sons and one daughter.

He was a Royal Arch Mason, and for many years belonged to the old Board of Trade, and also to the Chamber of Commerce, of Cleveland.

Mr. Morse was one of the oldest members of the American Society of Civil Engineers, having been elected a Member on July 12th, 1877. He was a Charter Member of the Civil Engineers Club of Cleveland, now the Cleveland Engineering Society.

PHILIP CHAPIN DAVIS, Assoc. M. Am. Soc. C. E.*

DIED MARCH 26TH, 1914.

Philip Chapin Davis was born on September 14th, 1881, at Kalamazoo, Mich., in which city he obtained his early education. In 1906, he was graduated from the Engineering Department of the University of Michigan, with the degree of Bachelor of Science in Mechanical Engineering. In September of that year, he entered the employ of the Thompson-Starrett Company, General Builders, and was with that company on several notable engineering problems, both in Chicago and New York, until August, 1911, when he became associated with the Jobson-Gifford Company of New York, as Superintendent of Construction in connection with the electrification of the New York, New Haven and Hartford Railroad, between New York City and New Rochelle, and also between Stamford and New Haven.

On October 29th, 1908, Mr. Davis was married to Miss Bertha Shean, of Kalamazoo, Mich., who, with two sons, survives him. Mr. Davis died at the Neurological Institute, New York City, on March 26th, 1914, following a year's illness from recurring attacks of pernicious anæmia.

Mr. Davis was a member of Anchor Lodge, No. 87, F. and A. M., and a member of the Sigma Chi Fraternity. He was a young man of exceptional ability, and his friends and associates feel deeply their loss on account of his untimely death.

Mr. Davis was elected an Associate Member of the American Society of Civil Engineers on June 4th, 1913.

* Memoir prepared by Erle K. Knight, Assoc. M. Am. Soc. C. E.

ROGER TIFFT HOLLOWAY, Assoc. M. Am. Soc. C. E.*

DIED MARCH 12TH, 1914.

Roger Tifft Holloway, the second son of Henry F. and Metta J. Holloway, was born on August 29th, 1885, in Columbus, Ohio. In 1887, the family moved to Montclair, N. J., and he was educated at the public schools of that place. He was graduated from the High School in 1904, and was President of his class during his Junior and Senior years. In the fall of that year, he entered Cornell University, from which he was graduated in 1908, with the degree of Civil Engineer. While at Cornell, Mr. Holloway was elected a member of the Alpha Delta Phi and of the Sphinx Head, a Senior society, and he also belonged to the Cornell Glee Club.

In August, 1908, Mr. Holloway was engaged by the Turner Construction Company, of New York City, as Assistant to the Superintendent on reinforced concrete work, remaining with the Company until January, 1909. From March to October, 1909, he was employed as Structural Detailer and Draftsman with the Hay Foundry and Iron Works, at Newark, N. J. In February, 1910, with the writer, he engaged in private practice, as a Consulting Structural Engineer, under the firm name of Mead and Holloway, continuing as a member of the firm for two years. During this time he prepared plans, estimates, etc., for numerous alterations and contracts, among which were plans and specifications for the steelwork for the Irvington School, the Nurses' Home in connection with the Presbyterian Hospital, in Chicago, Ill., the Dock Street Pier, Philadelphia, Pa., etc. He also acted in an advisory capacity on this work.

In June, 1912, Mr. Holloway severed his connection with the firm of Mead and Holloway to engage in the general practice of civil engineering. He was also the New York representative of the London firm of Bagley, Mills and Company, and until his sudden death which occurred at his home in Montclair on March 12th, 1914, from septic poisoning, following an attack of tonsilitis, he was engaged in preparing plans, specifications, estimates, etc., for a number of constructions and alterations in and around New York City.

Mr. Holloway was always courteous, and, in his short professional career, had established a reputation for painstaking care and accuracy which won him many friends. The aptitude shown by him in his profession was probably inherited, his father being a member of the American Society of Mechanical Engineers, and a great-uncle, Mr. J. F. Holloway, having served a term as President of that Society.

* Memoir prepared by Charles A. Mead, M. Am. Soc. C. E., supplemented by information on file at the Society House.

He was a member of the University Glee Club of New York, the Harlequins, of which he was President, the Montclair Athletic Club, the Alpha Delta Phi Club of New York, and Montclair Lodge No. 144, F. and A. M.

Mr. Holloway was prominent in the social activities of Montclair where his loss will be keenly felt. His engagement had recently been announced, and the wedding had been planned for the coming Autumn. Besides his parents, he is survived by two brothers and two sisters.

Mr. Holloway was elected a Junior of the American Society of Civil Engineers on May 31st, 1910, and an Associate Member on May 7th, 1913.

JOHANNES CORNELIS VLIEGENTHART, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 29TH, 1913.

Johannes Cornelis Vliegenthart was born in Delft, Holland, on July 15th, 1876. In 1893, he entered the Polytechnical School of Delft as a student of engineering, and was graduated therefrom in July, 1899, with the degree of Civil Engineer.

In September, 1899, he entered the Government service of The Netherlands as Assistant Engineer in the Royal Corps of Waterstaat, in charge of river improvement works of the waterway from the Port of Rotterdam to the sea, at Hook of Holland and Hansweert. This work included dredging, constructing groins for regulating the channel, etc.

In November, 1901, Mr. Vliegenthart was appointed Chief Engineer of the Haiho River Conservancy Commission, with headquarters at Tientsin, China. This Commission was appointed by the Peace Protocol after the Boxer Insurrection of 1900, for the purpose of dredging and regulating the Haiho River, with a view to making it navigable from Tientsin to the sea for steamers drawing from 10 to 14 ft. of water. Under his direction three channels were constructed of a total length of 4 miles, thereby shortening the river by 15 miles and eliminating ten sharp bends. In addition to this work, Mr. Vliegenthart had charge of a survey of part of the Province of Chili, which included the cities of Peking, Tientsin, and Paoting. This survey was made chiefly for the purpose of studying the courses of the various tributaries of the Haiho River, looking to the improvement of such tributaries. He had promised to read a paper before the Koninklijk Instituut van Ingenieurs (Royal Institution of Netherland Engineers) on the great engineering works in North China in which he had had such a prominent part, but the fulfillment of this promise was prevented by his death.

* Memoir prepared by the Secretary from information on file at the Society House.

With the exception of a vacation in 1906, he remained in China until early in 1913, when he resigned his position with the Haiho Conservancy Commission and returned to his home in Holland. In September, 1913, on the election of the well-known engineer, Mr. R. R. L. de Muralt as a Member of Parliament, Mr. Vliegenthart was appointed to succeed him as Engineer of the "Waterschap Schouwen" (Hydraulic Company, Isle of Schouwen, Province of Zeeland). He remained in this position until his death which occurred on October 29th, 1913, at Zierikzee, Holland.

He belonged to that group of Netherlanders who have raised the reputation of Dutch engineers in foreign countries to a high standard, and his name will be held in honored remembrance as one of the pioneers who co-operated in the development of China.

Mr. Vliegenthart was elected an Associate Member of the American Society of Civil Engineers on June 5th, 1907.

EXTERNAL CORROSION OF CAST-IRON PIPE.

By Marshall R. Pugh, M. Am. Soc. C. E.

To be Presented October 7th, 1914.

Synopsis.

Cast-iron pipe is in such general use that a knowledge of its strong points, its limitations, and the precautions necessary to insure its durability under certain conditions, is of the highest importance to the engineer.

The purpose of this paper is to warn the engineer of conditions where special protection is needed against external corrosion, and to suggest preventive measures adapted to different cases, in the hope of bringing out more information in the discussion.

Tuberculation and electrolysis from stray currents have been studied elsewhere at length and will not be discussed herein.

Examples of the great durability of cast-iron pipe are first given, after which other instances are cited in which it has deteriorated rapidly. Mention of the composition of cast iron and the theories of its corrosion is followed by a study of conditions contributing to, and inhibiting, corrosion.

In the light of this information, reasons are sought for the de-

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

terioration observed in typical cases; and then precautionary and preventive measures are considered.

Introductory.

Records of the facts relating to the corrosion of cast-iron pipe are so scattered (frequently consisting of incidental references in articles on unrelated branches of engineering), and so much of the literature is found only in publications familiar chiefly to the chemist and physicist, that, abandoning any effort at originality, it seemed worth while to gather these scattered facts and what little is known, in the hope that additional information might be brought out and light thrown on many perplexing problems; and that the whole might be placed before the engineer in accessible form.

"There is no limit to the life of cast-iron pipe", says a recent advertisement in a technical journal, and this undoubtedly voices the opinion of many well-informed persons. Opposed to that we find the following: "The relatively high rate of self-corrosion [as distinguished from electrolytic corrosion] of cast iron as compared to the other kinds of iron tested is contrary to the generally accepted idea that cast iron is more resistant to self-corrosion than wrought iron."*

This paper will be confined entirely to a study of the external corrosion of cast-iron pipe, though, obviously, many facts must be applicable as well to internal corrosion. As stated, electrolysis from stray currents has already been dealt with so fully that it will not be taken up. Tuberculation has been studied exhaustively,† and internal corrosion and hot water troubles have been investigated very ably.‡

The ancients were unacquainted with pipe of this material, as the art of casting iron was unknown until the 14th or 15th Century. The Romans, in the time of the Cæsars, used pipes of stone, bronze, and lead. Fig. 1 shows a Roman, bored stone pipe, and Fig. 2 a lead pipe, with a section the actual size of the pipe. These pipes were always oval in shape, and were made of a sheet of lead bent

EXAMPLES OF DURABILITY OF CAST-IRON PIPE.

We cannot go back so far in our study of the life of cast-iron pipe. The earliest records which appear to be authentic relate to several old pipes of various diameters laid, by order of Louis XIV, near

* "The Two Books on the Water Supply of the City of Rome, by Sextus Julius Frontinus", translated by Clemens Herschel, M. Am. Soc. C. E., Boston, Dana, Estes & Co., 1899.

Paris, from the reservoirs of Picardie to those of Montbauron, together with the spring water conduit, the whole supplying the town and parks of Versailles. According to the Ministry of Public Instruction and Art,* these were laid between 1664 and 1688, or from 226 to 250 years ago. They aggregate about 8 000 m. (26 000 ft.) in length, and are still in use. The great fountains at Versailles, one of which, the fountain of Neptune, is shown in Fig. 10, are supplied with water through three pipes, 20 in. in diameter, which bring the water from the Park of the Trappists to the reservoirs of Montbauron; two 20-in. and three 13½-in. pipes leading from the reservoirs to the gate-house; and two 20-in. pipes and a 13½-in. pipe leading from the reservoirs of Gobert to the reservoirs of l'Aile. These aggregate 27 500 ft. in length, were laid in 1685, 229 years ago, and are still in use. Two years later, or in 1687, the conduit of Chevreloup, 13½ in. in diameter and 11 500 ft. long, was laid from the reservoir l'Aile to the Trianon.

"All of these pipe lines consist of pipes one meter in length, joined by means of bolted flanges. They are of considerable weight, and still serve their purpose satisfactorily.

"The few repairs which have been required have generally been necessitated by the bad condition of the flange bolts, which have rusted out."*

At Clermont-Ferrand, Department of Puy-de-Dôme, on September 14th, 1746, the Commissioners of Fountains made an agreement with a Parisian iron merchant, Sieur Marchais, for furnishing about a mile of 5 or 6-in., cast-iron pipe to supply water to the fountains. This pipe was laid in 1747-48. The lower portion, in the plain, was under quite heavy pressure, and was $\frac{8}{10}$ in. thick; where the pressure was less, the thickness was only ½ in. These pipes were in 3-ft. lengths, flanged, and with a lead gasket sometimes as thick as $\frac{7}{8}$ in. In 1867, the system was paralleled by new mains, but much of the original pipe is still in use.

At Saint Etienne, in 1904, there were cast-iron pipes which had been in service since 1782, or 122 years.*

A few years ago, the City of Paris* abandoned the Chaillot Pumping Station, the first erected for supplying that city with water. The

* "The Life of Cast-Iron Pipe", by C. Cavallier, *Journal*, New England Water Works Assoc., June, 1904, p. 218.

intake, consisting of flanged cast-iron pipe extending out into the Seine, was removed after having been immersed in the river for more than a century. When removed the pipes were found to be so well preserved that they could readily have been used again, except for the fact that they were of an antique and obsolete pattern. After removing the scale and shellfish coating from the exterior, the inscription, "CREUSOT, AN 10", in raised letters, could be readily seen. This date corresponds to the year 1802 in the present calendar.

The metal was a gray, cast iron of excellent quality. No alterations of either the interior or exterior appeared after its 100 years of service, and the fractures were as sharp as those from a fresh casting.

London and Glasgow have a record of 120 years of service for cast-iron pipe. The first extensive works in the former city were built by Sir Hugh Middleton between 1609 and 1613. As early as 1746, the Chelsea Water Company, of London, laid a 12-in. flanged, cast-iron pipe, which was relaid in 1791 on account of the joints "being perished." It was the engineer of that water company, Mr. Thomas Simpson, who designed the first bell and spigot pipes. This was about 1785, at which time an experimental section with lead joints was laid.*

As a rule, however, London was supplied with water through wooden pipes until about 1820.

In the United States, the earliest pipes were of bored logs. Philadelphia adopted them, although, in 1804, a length of about ¾ mile of iron pipe was laid as an experiment. The new Fairmount Water-Works in that city had a distribution system of cast-iron pipes, which was the first in America, at all events on an extensive scale.

These pipes were imported from England, and were of the bell and spigot type, in 9-ft. lengths. A curious feature about them was that each length had three or four ribs or rings about it, approximately 1½ in. wide, which were presumably to afford places with heavier walls in which to tap the pipe.† These pipes are of particular interest owing to the fact that they are still in use after 95 years, with every evidence of continuing to give a good account of them-

* "The Development of Water Supplies and Water-Supply Engineering," by Frederic P. Stearns, Past-President, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LVI, p. 455.

† Information regarding Philadelphia water pipes was furnished by the Bureau of Water of that city.

selves. Though forming only an infinitesimal portion of the present distribution system, they, nevertheless, constitute quite a considerable mileage.

A few of these pipes are noted in order to give an idea of their character: A 4½-in. cast-iron pipe on Chestnut Street, from Broad to 15th Street, laid in 1817, was removed only recently. A 22-in., cast-iron main leads from Fairmount Basin to Green Street, to Pennsylvania Avenue, to Callowhill Street. It then reduces to a 20-in. main leading to Broad Street and thence to Chestnut Street. This pipe was laid in 1819, and, with the exception of a portion which was removed in 1897 on account of the construction of the Pennsylvania Avenue Subway, is still in use. Mains on Market Street, from Juniper to Broad Streets, laid in 1820, from Eleventh Street to Juniper Street, laid in 1823, and from Water Street to Eleventh Street, laid in 1822, were in good condition when removed in 1907 to make way for the Market Street Subway. Mains, 6 and 10 in. in diameter, on Second Street, between Greenwich Street and Lehigh Avenue, were laid between 1823 and 1852; 8-in. mains on Front Street, between Wharton Street and Laurel Street, were laid at various dates between 1822 and 1834; one 10-in. main on Chestnut Street, from Front Street to Broad Street, was laid in 1821 and 1823; and a 20-in. main on Fifteenth Street, from Callowhill Street to Chestnut Street, was laid in 1829. All these mains are still in use.

This list might be extended to several pages, but it serves to show that a century's use has not rendered these pipes unfit for service. Virtually the whole of the old distribution system laid at that time has given an equally good account of itself.

The late James B. Francis,* Past-President, Am. Soc. C. E., cited the case of Lowell, Mass., as follows:

"It is within my experience and knowledge that pipes at Lowell, which were obtained from Philadelphia in 1830, were then intended to be used under a pressure of 150 feet head, and are now in use under 200 feet head, without any signs of failure after sixty years' use."

Even when immersed in the fresh water of streams and rivers, this resistance to corrosion is manifested. Cast-iron cannon taken

* *Transactions*, Am. Soc. C. E., Vol. XXIV, p. 261.

from a vessel sunk in the Delaware River for more than 40 years were perfectly free from rust.

Summing up what has been observed, it may be said that our experience of 250 years with cast-iron pipe has not been sufficiently long to establish just what its life is.

Examples of Deterioration of Cast-Iron Pipe.

A knowledge of this fact, however, may lead to very mistaken conclusions. One of the earliest observations relating to the rapid deterioration of cast-iron pipe was that of Mr. Thomas Duncan, who, in 1853, in describing the Liverpool Corporation Water-Works, said:

"During the process of taking up and adjusting the pipes in the lower districts, near the margin of the docks, where the soil is impregnated with muriate [common salt] they were found, in many instances, to have become so soft, that they could easily be cut by a knife. This was found to be the case where they had not been laid for more than twenty years; whereas, in the higher districts, where they had been laid for nearly fifty years, they were found to be as good as when first laid down. In all instances the hardest pipes had deteriorated least, and were found cleanest on the inside."*

In other words, under certain conditions, cast-iron pipe is not durable, unless protected. Therefore, it is of great importance to the engineer to determine just what those conditions are, and how to guard against them.

The salt of the ocean is particularly destructive to cast iron, and its action is manifested in a peculiar way, differing materially from ordinary rusting, scaling, and pitting.

In contrast to the case in which cast-iron cannon removed from the fresh waters of the Delaware River were found to be free from rust, Major-General Pasley† stated that the cannon of the *Royal George,* which had been sunk in the ocean for 62 years, and of the *Edgar,* which had been similarly submerged for 133 years, had been examined by him. The cast iron had generally become so soft that the metal, which resembled plumbago in appearance, could be readily cut with a knife. The cast-iron shot became red hot on exposure to air, and fell to pieces. The cannon hardened after a time, and the late William J. McAlpine,‡ Past-President, Am. Soc. C. E., said

* *Minutes of Proceedings*, Inst. C. E., Vol. XII, p. 487.
† *Minutes of Proceedings*, Inst. C. E., Vol. III, p. 86.
‡ *Transactions*, Am. Soc. C. E., Vol. I, p. 23.

that they were again fired. Be that as it may, the cast-iron guns from some ancient pirate ship were brought up from the ocean depths off Holyhead in 1822, after the lapse of a century. They were quite soft, but hardened so much on exposure to the air that they were used to fire salutes to King George IV, when he passed through Holyhead on his way to Dublin.* These old guns were said to have given louder reports than any others!

The chemist, Berzelius,† also refers to the curious heating of cannon balls, and states that some which were raised at Karlskrona, from a ship that had been sunk for 50 years, were found to have been converted into a porous, graphitic mass which heated spontaneously on exposure to air for 15 min.

It is well known that iron filings will burn in the flame of a candle, and that very finely divided iron, obtained by the reduction of its oxides in hydrogen, is pyrophorous, that is to say, it ignites spontaneously on exposure to air. These cannon balls, therefore, may have contained a remnant of metallic iron in an exceedingly fine state of subdivision. The heating may also have been due to the rapid change from ferrous to ferric hydrate on exposure to air, or to a combination of the two causes. Just why the shot should heat up and fall to pieces, when the cannon themselves did not, is difficult to explain.

The corrosive action of sea water is not uniform under all conditions, but may be materially accelerated or retarded. A case of this sort is cited by Mr. Robert Mallet‡:

"Iron under certain circumstances is subject to a peculiar increase of corrosive action—as, for instance, cast-iron piling at the mouth of tidal rivers—from the following cause. The salt water being of greater density than the fresh, forms at certain times of tide an under current, while the upper or surface water is fresh; these two strata of different constitution coming in contact with the metal, a voltaic pile of one solid and two fluid elements is formed; one portion of the metal will be in a positive state of electrical action with respect to the other, and the corrosive action on the former portion is augmented. The lower end of an iron pile, for instance, under the circumstances just mentioned, will be positive with respect to the other,

* Rennie, *Minutes of Proceedings*, Inst. C. E., Vol. IV, p. 333.
† Traité de Chimie, 1831, Vol. III.
‡ *Minutes of Proceedings*, Inst. C. E., 1840, p. 71.

and the corrosion of the lower part will be augmented by the negative state of the upper portion, while the upper will be *itself* preserved in the same proportion."

This statement would seem to be borne out by observations on the Brandywine Lighthouse,* situated on a shoal of that name in Delaware Bay, 8 miles inside the Capes. It is founded on nine, hammered-iron, screw-piles, surrounded by fifty-two rolled-iron, fender-piles. It was built in 1849-50, in about 6 ft. of water, but at times the scour and shifting sands have varied this depth materially. In 1873, an examination by a diver revealed the fact that the most serious corrosion was below the surface of low water, beyond the action of the atmosphere. In 1879, one of the fender-piles, together with a portion of the cast-iron socket, was broken off by ice. The outer $\frac{1}{8}$ in. of this casting consisted

"of a soft dark gray coating of metamorphosed iron, which could be removed readily with the finger-nail, but the piece retained the sharp outlines of its original form. The coating became hard after exposure to the air and did not separate from the iron, but the iron seemed rather to have become softened by the action of the water on its surface. * * *

"No greater deterioration, where the wrought and cast iron were in contact, was observable."

Cases occur, and with considerable frequency, where trouble has resulted from laying cast-iron mains in saline soils.

In 1902, the Elizabethtown Water Company, Elizabeth, N. J., laid about 2 miles of 6-in., cast-iron main across salt meadows. It was ordinary coated water pipe, about 0.45 in. thick, and was laid about 8 in. below the surface of a salt marsh.† The surface of the marsh was about 18 in. above ordinary high water, and, therefore, was covered at times by salt water. The nearest trolley is about 3 miles away, so that stray currents have nothing to do with the observed deterioration of the pipe. In 1909, or only 7 years after it was laid, the pipe began breaking, under a pressure of 40 lb., and it became necessary to renew the whole line in 1912, after a life of only 10 years.

Internally, the pipe was in good condition. The external appearance was equally good, there being an entire absence of pitting. On

* *Proceedings*, Engrs. Club of Philadelphia, 1884, p. 129.

† Information furnished by Mr. D. H. Townley, Superintendent, Elizabethtown Water Company.

closer examination this appearance was found to be deceptive, for, in many places, sometimes the top, sometimes the bottom, and, at other times, the sides, were found to have large spots where the iron appeared to be leached out, so that it could be cut like putty, or rather like soft graphite, which it strongly resembled in appearance. This action was not regular, sometimes skipping several feet, but was worst at the bottom of the pipe. In some instances, these soft places had been eaten completely through the walls of the pipe, which, although not pitted or swelled out, had entirely lost all the characteristics of iron. After exposure to the air, this metamorphosed iron hardened, just like the cannon used in saluting King George IV at Holyhead.

At Perth Amboy, N. J., similar trouble was experienced. A 16-in. main, crossing a salt meadow for some 3 500 ft., had to be abandoned altogether in less than 20 years. Mr. A. H. Crowell, Superintendent of the Water-Works, under date of March 20th, 1913, says:

"Our second main, a 24-in., laid under the same conditions [as the 16-in. main] about seven years ago, now shows evidence of the same deterioration, softening in spots so that it may be pared with a knife on the exterior. This line the Board has decided to uncover and leave exposed in open trench to the flow of the tides, our experience having shown that pipe when so laid exposed to the light and air is not affected; in other words, we have reached the conclusion that this particular deterioration occurs from chemical action due to contact of roots of salt grasses.

"In connection with the deterioration, one peculiarity noted is that when such pipe is removed and exposed to the light and air for a period of several weeks it will harden and ring apparently sound."

This pipe, which was laid in black meadow muck from which salt grass is cut, is buried with 3 ft. of cover. The meadow is completely submerged at extreme tides, with an ordinary range of about 4 ft. The pipe was ordinary gray cast iron, tar-coated, weighing 140 lb. per ft., and the deterioration occurred at all points, but principally on the top and upper sides. As in the Elizabeth pipe, the exterior did not pit, but deterioration occurred from softening in spots which finally blew out.

At Atlantic City, N. J.,* the water supply is delivered to the city from the Absecon Pumping Station, the mains leading through salt

*Information furnished by Mr. Lincoln Van Gilder, Engineer and Superintendent, Water Department.

marsh for a distance of 22 000 ft. In 1882, a 12-in. cast-iron main was laid, which, in 1888, was paralleled by a 20-in., cast-iron main; and, in 1901, the capacity was further augmented by laying a 30-in. steel main alongside the others. In 1911, a 48-in., wood stave main was laid parallel to the preceding three for about 7 000 ft., after which it takes a different route for the remainder of the line. Both the cast-iron mains are soft in spots, and blow out from time to time in places, under a normal pressure of 50 lb. The deterioration is precisely like that noted at Elizabeth and at Perth Amboy. The steel pipe is even less satisfactory. Though laid at a later date than the two cast-iron mains, it is rapidly deteriorating, and 6 000 ft. of it are now out of service.

The top of each of the two cast-iron mains is about 1 ft. below the surface of the meadow; the steel main is about half its diameter below the surface, and the top is covered with meadow sod.

At Richmond, Va.,* about 400 ft. of 6-in., cast-iron pipe, laid in a salt blue marl, in 20 years, became soft enough to cut with a knife, the action appearing to be equally great at its top, bottom, and sides. A trolley track, 450 ft. distant, may possibly have contributed to the disintegration.

Trouble has been experienced also from saline soils at points remote from the ocean. At Syracuse, N. Y., there are salt springs which have been used in the manufacture of salt since their discovery by the Jesuits in 1654. They are situated along the shores of Onondaga Lake, and, in 1797, were taken over by the State, which passed laws governing the manufacture of salt.

The Bureau of Water† of Syracuse has had much trouble from the corrosion and disintegration of water pipe in the salt lands. A line of pipe runs in a very low section of these lands, the major part of which is under water a large portion of the year. The part which is continually submerged, however, has not disintegrated, but that adjacent to it, where the main was laid about 1904, began to fail after several years' service. The corrosive action appears to have been similar to that noted heretofore. The pipe was sound in parts, and at the leaks it could be cut with a knife. The salt has been for a century at the point where the disintegration occurs.

* Information furnished by Mr. E. E. Davis, Superintendent, Water-Works.
† Information furnished by Mr. George A. Glynn, Superintendent.

A third soil destructive to cast-iron pipes is also noted by Mr. Glynn as occurring at Syracuse. He says, in a letter:

"Since submitting this matter to you and Dr. Pattee, I have observed two cases of disintegration in differents parts of the town, the pipe being eaten precisely as that in Spring Street. In each case the soil above the pipe was composed in the main of coal ashes and apparently the constant trickle of water had created some chemical action which ate the pipe. As a layman, I have concluded that coal ashes, where there is a possibility of a flow or trickle of water through them, are responsible for this particular kind of disintegration."

A. A. Reimer,* Assoc. M. Am. Soc. C. E., notes an instance in his experience where an 8-in. main, laid in clay and ashes—marl with some cinders mixed with it—went out of service every 6 months.

In Germany, R. Krzizan† cites a case where a portion of an asphaltum-coated, cast-iron, water main, which had been in service for 20 years, suddenly became defective. A number of conical holes were scattered irregularly over the surface and were surrounded by graphite-like material containing particles of metallic iron. The composition of this corroded material is given in Table 1.

TABLE 1.—ANALYSIS OF CORRODED GERMAN WATER PIPE.

Metallic iron	5.98
Ferric oxide and hydroxide	34.09
Ferrous phosphate	9.63
Ferrous silicate	37.16
Ferrous sulphate	0.47
Carbon	11.42
Sulphur	0.097
Manganese	1.362
Copper	0.296
	100.505

There was nothing in the water running through the pipe to account for this formation, but crystals of gypsum were distributed irregularly in the clay in which the pipe was laid. Krzizan attributes the corrosion to local currents set up by contact between the graphite particles and the iron, in the presence of a solution of calcium sulphate at the points where the crystals of gypsum were contained in the clay adjacent to the pipe.

* *Proceedings*, Am. Water Works Assoc., 1910, p. 263.

† *Zeitschrift* für öffentliche Chemie, Vol. XVIII, p. 433.

A question arises as to what effect the alkali soils of the West would have on cast-iron pipe, and it is hoped that information on this point may be brought out in the discussion of this paper. In the effort to obtain some facts bearing on this phase of the subject, the soil survey of the Uncompahgre Valley, in Colorado, made by Messrs. Nelson and Kolbe for the United States Department of Agriculture in 1910, indicated that Montrose, on the banks of the Uncompahgre River, had areas of such high alkalinity that experience there would be useful in giving an idea of what might be expected in such cases.

"The source of most of the alkali of this area is the underlying shales, and wherever they are near the surface its presence is assured."*

The low valley soils are also in general heavily charged with alkali, the principal salts being sodium sulphate (Na_2SO_4); sodium chloride (NaCl), or common salt; calcium chloride ($CaCl_2$); magnesium chloride ($MgCl_2$); magnesium sulphate ($MgSO_4$); and sodium carbonate (Na_2CO_3), named in the order of the quantities in which they occur. An analysis of a typical alkali crust found on the surface of the soil is given in Table 2.*

TABLE 2.—ANALYSIS OF ALKALI CRUST.

Constituent.	Parts per 100 000.	Constituent.	Parts per 100 000.
Calcium (Ca)	Trace.	Chlorides (Cl)	2 280
Magnesium (Mg)	.....	Sulphates (SO_4)	8 320
Sodium (Na)	2 870	Bicarbonates (HCO_3)	2 120
Potassium (K)	250	Carbonates (CO_3)	1 160
			17 110

The greater part of Montrose is underlaid by soil having an alkali content of from 200 to 400 parts per 100 000. There is a small area at its southwest corner where the alkali runs up to 600 parts per 100 000, and another area in the northwest portion where it ranges from 600 to 1 000 parts per 100 000.

Mr. R. L. Smith, Superintendent of Water Supply, states that the system, which was built in 1888, consisted of 4, 6, and 8-in., wrought-iron pipe, which deteriorated so rapidly that it was all replaced either by cast-iron or wood stave pipe, except about 800 ft.

* "Soil Survey of the Uncompahgre Valley Area, Colorado," Nelson and Kolbe, Washington, 1912.

of the 8-in. pipe in the southwestern part, which is still in very fair condition. Cast-iron pipe which has been in use for nearly 20 years has appeared to be in an excellent state of preservation, wherever it has been examined, and has never given any trouble. The alkali soil, however, has been disastrous to the wire of the spiral-wound wood stave pipe. It was laid in 1905 and will have to be removed within the next couple of years. There are no trolleys, and the pipe is laid 4 ft. below the surface.

Before attempting to draw any conclusions from the facts presented, it will be desirable to consider first the composition and character of cast iron, and second, to review as briefly as possible the theory of its corrosion, and study some experimental data bearing on the subject.

The Composition of Cast Iron.

Cast iron is a substance of varied composition, both physically and chemically, so that some conception of its formation is desirable in considering its corrosion.

It is well known that common salt added to water progressively lowers its freezing point, until, with 23.5% of salt present, the whole mass freezes at —22° cent. This is said to be the "eutectic" composition, a term which is used of a compound substance that has a lower fusing point (or freezing point) than its components themselves. The freezing point is raised if either more or less salt is present.

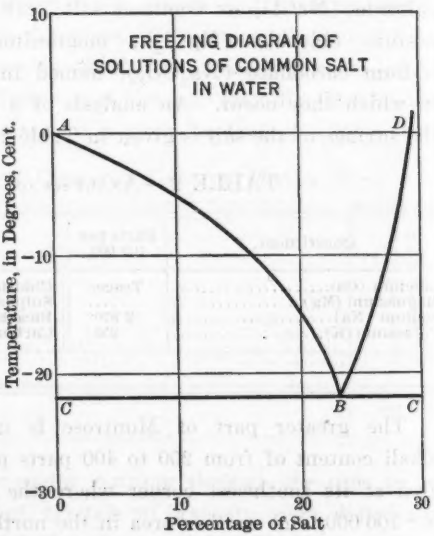

Fig. 3.

The whole is shown diagrammatically by Fig. 3.* In percentages less than the eutectic, crystals of ice form when the temperature falls to the points shown on the curve, *A-B*, the mother liquor be-

* "Cast Iron in the Light of Recent Research," Hatfield.

coming more concentrated, until the eutectic composition is reached, at which time the whole solidifies. This always occurs at a temperature of — 22° cent. If the original solution contains more than 23.5% of salt, the solution progressively freezes at the temperatures shown on the curve, *B-D*, pure salt being deposited and the mother liquor becoming less concentrated, until at — 22° cent., it diminishes in saline content to the eutectic composition, when, again, simultaneous freezing takes place. The line, *C-C*, shows the freezing point of the mother liquor. Under the microscope, it is seen that the ice is not homogeneous, but consists of innumerable plates of salt and ice in mechanical contact.

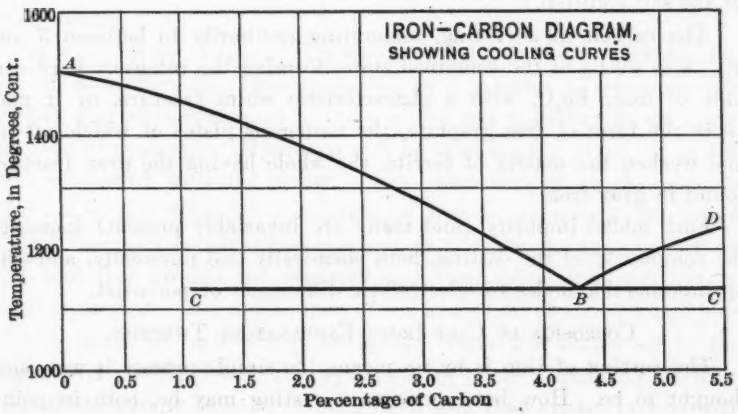

FIG. 4.

Pig iron, similarly, may be termed a frozen solution of carbon and iron. If no other impurities were present, it would contain 4.3% of carbon. Fig. 4* shows graphically how the addition of carbon lowers the solidifying point to *B*, or the eutectic, and then raises it to *D* as additional percentages are present, the line, *C-C*, indicating the constant solidifying point of the mother liquor at 1 135° cent. The free graphite found in cast iron, therefore, is due to the same action as the solid plates of salt frozen out of the water, with this important difference, that whereas ice does not retain any salt in solid solution, the solidified iron retains much carbon.

It has been known for a long time that in pig iron which has been heated considerably above its fusing point, the carbon tends

* "Cast Iron in the Light of Recent Research," Hatfield.

to separate in the graphitic form, whereas the same metal, heated to a lower degree, on cooling, would retain more carbon in the combined condition. Much study has been devoted to this obscure subject, and a series of modifications of iron and iron-carbon, all due to different conditions of heating and cooling, have been investigated, but it would be out of place to consider the subject in this paper.

To summarize briefly: the metal collecting in the bottom of a blast furnace is a saturated solution of carbon in iron, and as it cools to the solidifying point, carbide is thrown out of solution. This splits up into iron and carbon. Iron solidifies, the mother liquor splits up, and the same process is repeated. It is analagous to the behavior of the salt solution.

The carbon in a casting, amounting ordinarily to between 3 and 4%, may all be in the combined state, forming the intensely hard carbide of iron, Fe_3C, with a characteristic white fracture, or it may be in the form of free graphite, the numerous plates of which cut up and weaken the matrix of ferrite, the whole having the gray fracture found in gray iron.

Each added impurity (and many are invariably present) increases the complexity of the casting, both chemically and physically, and sets up innumerable nodes for electrolytic differences of potential.

Corrosion of Cast Iron: Explanatory Theories.

The rusting of iron is by no means the simple process it was once thought to be. How heterogeneous a casting may be, both in point of composition and in physical structure, has been shown. This adds materially to the difficulty, and explains the often apparently discordant results obtained by careful investigators.

Five separate theories have been advanced to account for the rusting of iron, but, at present, three of these have been practically eliminated, leaving only two over which the fight still wages: the acid theory and the electrolytic theory. The one undisputed fact is that iron cannot rust in air unless water is present, nor can it rust in pure water unless oxygen is present.

Mr. J. Newton Friend* has recently collated much scattered material, and has placed virtually all the researches hitherto made on this subject in the hands of the investigator. To his work, the writer is greatly indebted.

* "The Corrosion of Iron and Steel."

The Acid Theory.—This theory regards corrosion as resulting from an acid, usually carbonic, which unites with the iron to form ferrous carbonate ($FeCO_3$) or the soluble ferrous hydrogen carbonate ($FeH_2[CO_3]_2$), and the liberated hydrogen combines with any dissolved oxygen in the water to yield water. The oxygen of the air next converts the soluble iron salt into hydrated oxide, or rust, liberating the carbon dioxide (CO_2) which is now free to attack a fresh portion of iron.* With a supply of water and oxygen, a small portion of carbon dioxide could thus rust an indefinite quantity of iron.

The Electrolytic Theory.—This theory holds that the presence of an acid is not necessary to cause rusting, but regards the action as electrochemical.†

To state briefly a few of the fundamental principles, consider the case of two platinum plates immersed in a solution of common salt (NaCl), one plate connected to the positive and the other to the negative pole of a battery. Hydrogen will be immediately given off at the plate connected with the negative pole, and oxygen at the positive pole. If a few drops of a solution of litmus are added, the liquid around the positive plate becomes red, indicating the presence of an acid, and that around the negative pole turns blue, showing that an alkali is present. The appearance of the gases and of the red and blue color is noted at once when the battery wires are connected to the plates, even if the latter are separated by quite a quantity of solution, giving strong support to the supposition that matter travels with the current, part toward the positive and part toward the negative pole. Farraday named these moving portions of the solution "ions." A solution or a fused salt which conducts the electric current is termed an electrolyte.

If a steel knife-blade is immersed in a solution of copper sulphate ($CuSO_4$), iron dissolves and copper is deposited, the electric charge being transferred from the ions of copper to those of iron. Electrochemically, hydrogen is a metal, and is classed with copper in relation to iron. If, therefore, iron is placed in a solution containing hydrogen ions, a similar reaction will take place, iron being dissolved and hydrogen passing from the electrically charged or ionic state to the atomic

* Crum Brown, *Journal*, Iron and Steel Inst., 1888, No. II, p. 129.

† Whitney, *Journal*, Am. Chem. Soc., 1903, Vol. XXV, p. 394; Cushman, "The Corrosion of Iron," Public Roads Bulletin No. 30, Washington, 1907.

or gaseous condition,* and being deposited on the iron blade. Ferrous salts, as well as ferrous hydroxide, are rapidly oxidized to the ferric state, if air or oxygen is present.

It is a matter of common observation that, when iron rusts, it does not do so uniformly, but in patches and spots. Allerton S. Cushman, Assoc. Am. Soc. C. E., noticed that if this rusting took place in water or in a neutral solution of an electrolyte, such as salt, to which a little phenol-phthalein had been added, a pink color developed, and this was confined to certain nodes or spots. This pink color is a proof of the presence of hydroxyl ions, and thus indicates the negative poles. Professor Walker† suggested adding a trace of potassium ferricyanide to the solution, in order to show the positive poles. If iron goes into solution, ferrous ions must appear, which, with the ferricyanide, form Turnbull's blue. Walker further suggested stiffening the reagent with gelatine and agar-agar to preserve the effect produced. This reagent, which indicates at once the positive and negative poles, with the ferrous ions shown by blue at the positive and the hydroxyl ions by pink at the negative poles, was named ferroxyl by Mr. Cushman.

Later, the writer will show the behavior of some of the corroded water pipes when ferroxyl is applied.

Whatever may be the abstract facts concerning the electrolytic and acid theories, if absolutely pure iron, pure oxygen, and pure water are used, both reactions take place under actual conditions of corrosion.

Natural waters are usually charged with dissolved oxygen and carbon dioxide from the air, thus readily permitting the action of carbonic acid on the iron. Even the purest commercial wrought irons are not homogeneous, either physically or chemically, so that electrolytic action also comes into play.

Conditions Contributing to Corrosion.

Hale,‡ in studying experimentally the corrosion of iron pipes by water flowing through them, concluded that practically carbonic acid, coupled with dissolved oxygen, is a most potent factor in corrosion. The iron is dissolved as bicarbonate with the release of hydrogen:

$$Fe + 2H_2CO_3 = FeH_2(CO_3)_2 + H_2.$$

* Whitney, *Journal*, Am. Chem. Soc., 1903, Vol. XXV, p. 894; Cushman, "The Corrosion of Iron," Public Roads Bulletin No. 30, Washington, 1907.

† *Journal*, Am. Chem. Soc., 1907, Vol. XXIX, p. 1257.

‡ *Journal*, Am. Public Health Assoc., Vol. III, p. 1337.

About 20% of this hydrogen re-united with the dissolved oxygen in the water. The soluble iron bicarbonate was oxidized also by the dissolved oxygen to insoluble red oxide, setting free the carbonic acid:

$$4FeH_2(CO_3)_2 + O_2 + 4H_2O = 2Fe_2O_3 + 8H_2CO_3.$$

This freed carbonic acid again dissolves more iron and is again set free, until all the oxygen is exhausted. As a result of the catalytic action of the carbonic acid and water, a very large quantity of iron is corroded for each part per million of dissolved oxygen. Theoretically, 10 parts per million of dissolved oxygen produce 126 parts per million of Fe_3O_4, expressed as Fe; whereas, if the hydrogen were oxidized and not set free, the quantity oxidized by 10 parts of oxygen would be only 31 parts per million of iron. By experiment, Hale found that from 75 to 80% of the theoretical quantity of iron was actually oxidized.

Although, theoretically, the oxide is the final stage, the differing colors of red, green, brown, and black indicate that the iron exists in hydrated form, except when formed in the hot way.

Hale also found that the rate of corrosion increased proportionately to the increase of free carbonic acid. Analyses for soluble iron and dissolved oxygen proved that this increase was due to the fact that the carbonic acid dissolved the iron more rapidly, and more iron being in solution, oxidation is hastened.

The aqueous solutions of most acids dissolve iron. For example, if hydrochloric acid is used, ferrous chloride and hydrogen are the resultant products, the former oxidizing into ferric chloride in the presence of air. If only a trace of acid is present, the iron will be deposited from the solution as hydrated ferric oxide or rust.

Cast iron subjected to the slow action of dilute acids, as, for example, acid water from mines, retains unchanged the external shape of the casting, but the composition of the metal is altered, iron being removed in solution.

Very dilute solutions of alkaline hydroxides, such as sodium hydroxide (NaOH), or caustic soda, and calcium hydroxide ($Ca[OH]_2$), or slaked lime, rapidly absorb carbon dioxide, forming carbonates which in such dilute solution do not prevent the iron from rusting. On the contrary, by hastening the absorption of oxygen by the iron, they increase corrosion.

If a plate of iron is cleaned, weighed, and placed in a beaker with either water or a solution of a salt, and after remaining in the solu-

tion for some fixed period, is removed, cleaned, dried, and weighed, the loss in weight measures the quantity of corrosion.

Taking 100 as the rate of corrosion of pure iron in water, Fig. 5 shows the rates in varying strengths of salt (NaCl) and sodium sulphate ($Na_2SO_4 10H_2O$), according to the experiments of Friend and Brown.* The surprising fact is that, whereas dilute solutions of these salts increased the corrosive action of water, stronger solutions exerted less corrosive action on pure iron than water alone. This bears out the experiments of Adie, made some 69 years ago.† He took weighed pieces of wrought and cast iron; immersed some in pure water and some in saturated solutions of salt, and after the lapse of several days, re-weighed them, with the results shown in Table 3.

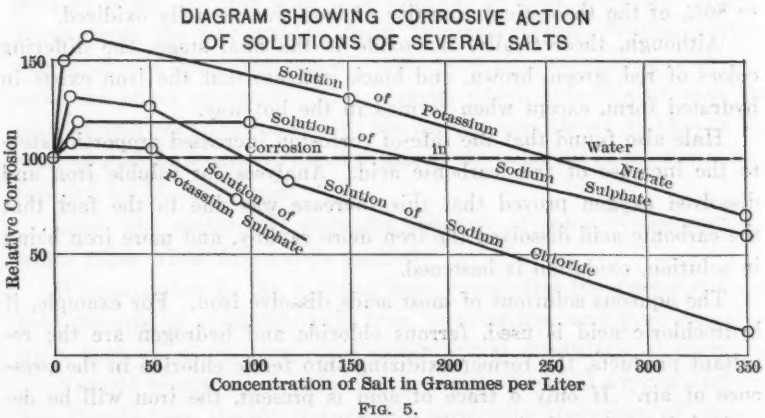

FIG. 5.

TABLE 3.

Conditions of the experiments.	Loss in fresh water, in grains.	Loss in salt water, in grains.
Twenty pieces of wrought iron, weighing 374 grains, exposed for 80 days	1.9	0.1
Three rods of cast iron, weighing 787 grains, exposed for 62 days	1.6	0.4

Both kinds of iron were corroded much more in the fresh water than in the saturated solution of salt water. Adie attributed this to the decreased solubility of oxygen in salt solutions. Friend proved experimentally that, in the absence of air, solutions of sulphates and chlorides of sodium and potassium have no action on pure iron.

* "Corrosion of Iron and Steel," by J. Newton Friend, 1911.
† *Minutes of Proceedings*, Inst. C. E., 1845, Vol. IV, p. 323.

Rain-water, particularly in thunder-storms, contains nitric acid or nitrates, and polluted waters also may contain nitrates and nitrites in solution. The curves on Fig. 5, showing the corrosive action of potassium nitrate and of potassium sulphate, also from Friend and Brown, are interesting, the more so as it is very dilute solutions of these substances which are ordinarily encountered. As these curves show, their corrosive effect is then at a maximum.

Magnesium and ammonium chlorides are found to corrode iron, even in the absence of air. This gives a clue to the particularly destructive effect of sea water (which contains magnesium chloride) on cast iron, even at great depths below the surface, where fresh water would not contain enough dissolved oxygen to exert any deleterious influence on the iron.

With mixtures of two or more electrolytes in one solution, the subject becomes so broad that a vast amount of investigation remains to be done.

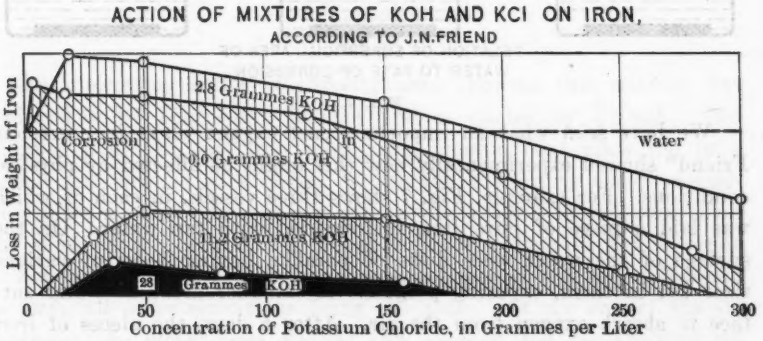

FIG. 6.

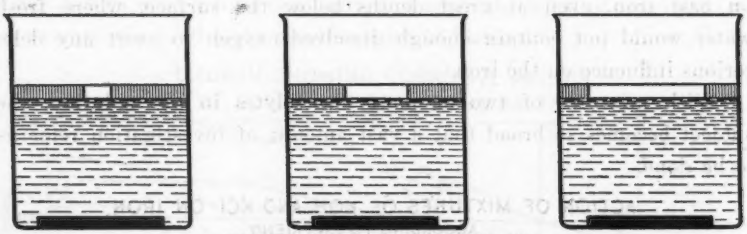
It is very important, however, to have some idea of what occurs under such circumstances. Friend* placed 36 pieces of pure iron foil in a series of hard glass beakers, the first containing water, and the others containing water in which varying quantities of potassium chloride and potassium hydroxide (caustic potash) were dissolved. These were allowed to remain 28 days, after which the iron plates were removed, cleaned, and weighed. The results are shown graphically by Fig. 6. From this it will be seen that pure water corrodes iron much more rapidly than water containing caustic potash; that

* *Journal*, Iron and Steel Inst., 1911.

the corrosive action is greatly increased by the presence of potassium chloride; that increasing quantities of chloride first increase and then gradually diminish the intensity of corrosive action; and that increasing quantities of caustic potash, after a temporary increase in dilute solution, diminish corrosive action, finally inhibiting it altogether. It is this action of alkalis which explains the protection of steel and iron in concrete, the alkalis in the cement exerting a protective action, in spite of the simultaneous presence in the cement of corrosive electrolytes such as sulphates of magnesium and alkaline earths.



RELATION OF SUPERFICIAL AREA OF WATER TO RATE OF CORROSION

FIG. 7.

We have seen what an important part oxygen plays in corrosion. Friend* showed experimentally how this might be affected by physical conditions. For example, Fig. 7 shows three vessels, in each of which was laid a piece of pure iron foil covered with tap water. On the surface of the water were disks of paraffin, having holes of various sizes cut in them, exposing progressively smaller areas of water surface to absorb oxygen from the air. After 5 days, the pieces of iron foil were weighed, and the relative results are given in Table 4.

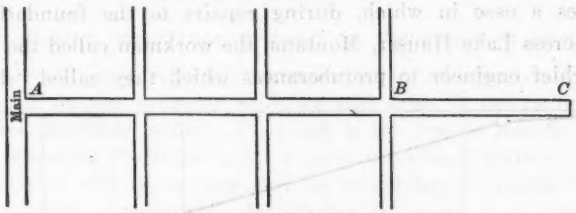
TABLE 4.—RELATION OF SUPERFICIAL AREA OF WATER TO RATE OF CORROSION.

Superficial area of water, in square centimeters.	Relative corrosion.
56.8	100
12.6	58
0.8	14

The rate of motion of water also has a bearing on the rapidity of corrosion. In certain circumstances, it causes greater aeration,

* "The Corrosion of Iron and Steel," p. 75.

and it also brings a constantly renewed supply of air to the rusting metal. Mr. M. B. Jamieson* gives an interesting example of this, illustrated in Fig. 8, in which a main, running from a larger main at *A* to a dead end at *C*, had a number of side branches taken off it. There was, therefore, a continually diminishing quantity of water and a diminished rate of flow, the greater the distance from *A*. After 45 years of use, the pipe was found almost choked with rust at *A*, but with less and less of it as the point *C* was approached. The pipe was practically clean from *B* to *C*.



WATER MAIN, SHOWING RELATION OF VELOCITY TO CORROSION

FIG. 8.

An interesting series of investigations showing this relation was undertaken by Heyn and Bauer,† and is quoted by Friend. Two weighed plates of cast iron were hung from a bent glass rod in a beaker and covered with water. A stream of running water was admitted by a glass tube and the excess was allowed to run away over the sides of the beaker, the operation being continued for a period of 3 weeks. Several beakers were used, the rate of flow being different in each, all other conditions being the same. At the end of the experiment, the plates were cleaned and weighed, the loss showing the corrosion. Fig. 9 shows the results of these experiments. It will be seen that a gentle flow increases the corrosion to more than eight times that in still water, but that it gradually diminishes as the rate of flow increases.

It is a noticeable fact that in most cases of bad pipe corrosion that have come to the writer's notice, not only was there salt water, aeration, and more or less motion in the water, but the pipes were laid, as a rule, in muck with rank swamp vegetation and life in close contact with the metal. The action of living matter, therefore, becomes

* *Minutes of Proceedings*, Inst. C. E., 1881, Vol. LXV, p. 323.

† *Mitteilungen* aus dem Königlichen Materialprüfungsamt, Berlin, 1910, Vol. XXVIII, p. 93 *et seq.*

a subject of interest, and will be found to merit careful consideration in many instances in which it has not hitherto been given a thought.

The direct action of any organism is doubtful, although it is known that organisms do occur in the tubercles forming on the inside of water mains. Dr. Brown* states that "Organisms are found in some incrustations and may modify their composition; on the other hand, incrustations are often free from every trace of life." Mr. Richard Gaines† found it probable that certain sulphur bacteria were responsible in part at least for rust tubercles and pitting in conduits. He also cites a case in which, during repairs to the foundations of a bridge across Lake Hauser, Montana, the workman called the attention of the chief engineer to protuberances which they called "shell rust"

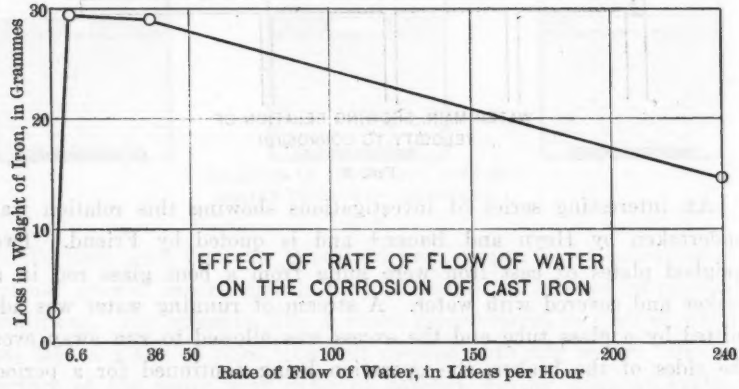


FIG. 9.

and which were found scattered over the surface of submerged steelwork. Schorler identified in this rust *Gallionella ferruginea* in large quantities. Apparently, the iron is dissolved by some acid secretion from these organisms, and, in this instance, the structural damage to this bridge which had only been in service for one year, had been enormous. It is even necessary to consider the earthworm. It has been estimated that, on an average, some 25 000 worms exist in every acre of soil. Darwin‡ concludes from his observations that each worm annually ejects 20 oz. of soil as castings, which means that 15 tons of soil in every acre of land pass through the worms each year. These castings are acid when fresh, and contain also small quantities of

* *Minutes of Proceedings*, Inst. C. E., Vol. CLVI.
† *Chemical News*, 1910, Vol. CI, p. 205.
‡ "Vegetable Mould and Earthworms."

ammonia. With 15 tons of acidified soil per acre per annum, with a small admixture of ammonium salts, there may well be a corrosive action on any embedded iron.

Darwin placed some worms in a pot of sand which, owing to the presence of ferric oxide, was red in color. The sand which passed through the worms and was found in their burrows, was bleached, and on microscopic examination, it was found that the ferric oxide was completely dissolved. Acetic acid scarcely produced any effect on this sand, yet the acid secretions of the worms decolorized it effectually.

Of still greater importance, probably, is the action of plants:

"Young roots, and especially root hairs, in addition to exhaling carbonic acid, excrete stronger acids or acid salts by means of which they dissolve insoluble bodies. That this is the case is readily demonstrated by allowing the roots to grow upon a polished plate of marble, when the latter will be so corroded as to exhibit an etched pattern showing the path of the roots. By placing the roots upon paper dyed with litmus or other sensitive indicator their acidity may readily be demonstrated. Furthermore, when plants decay, humus acids result which are powerful solvents."*

Our knowledge of the humic acids is very meager. It has been generally considered that they had an important rôle in the corrosive action of swampy waters. J. W. Ledoux,† M. Am. Soc. C. E., was troubled with the corrosive action of water at Charleston, S. C. This water was obtained from a reservoir covering 2 300 acres, and submerging a large quantity of peaty matter, much of it 15 ft. deep, a large part of the water-shed of some 49 sq. miles being low and swampy. He made a series of tests by boiling weighed pieces of piano wire in 500 cu. cm. of the water. This was done with raw water, water previously boiled to free it from oxygen and carbonic acid, and water to which various alkalis had been added. The loss in weight of the wire determined the relative corrosion. He was

"unable to determine whether ionization is the cause of the trouble, but rather believes in the theory that the raw water contains organic compounds which are corrosive in effect and with the elimination of organic matter as the result of the use of sulphate of alumina and filtration, these effects largely disappear."

* Friend, "Corrosion of Iron and Steel," p. 105.
† *Engineering Record*, Vol. LX, p. 701.

The indirect action of humus may be extensive under certain conditions. Jodidi* refers to the fact that the amount and nature of humus formed depends on the organic materials which undergo humification, on temperature, moisture, aeration of soil, presence of salts, acids, etc., and the character and quality of microbes present. The comparatively easily soluble products are leached out, and the less soluble ones accumulate in the humus. The humus is further oxidized by the action of air; the carbon to carbon dioxide; the hydrogen to water; the nitrogen to nitric acid; and the sulphur to sulphuric acid; and putrefaction leads to a number of secondary products, such as amino acids and acid amides.

How important these acids may become practically is illustrated by some recent experiences in Illinois. Clifford Older, Assoc. M. Am. Soc. C. E., in a paper† before the Illinois Society of Engineers and Surveyors, says:

"In southern Illinois a peculiar condition exists which undoubtedly has a material bearing on the corrosion of steel structures. In that portion of the State popularly known as Egypt, a large proportion of the surface soil, when tested, shows a marked acid reaction. This condition exists generally throughout the greater part of the state which lies south and east of the Kaskaskia River and south of the latitude of Mattoon. To a less marked degree, the soil is acid in many places elsewhere in the state where land has been farmed for 50 years or more.

"This acid condition does not exist for a depth of more than a few inches, and steel buried at a greater depth does not seem to exhibit any unusual tendency to corrode."

He notes the complete destruction of the webs of I-beams and channels having a thickness of ¼ in. in from 10 to 12 years.

Dr. Adeney ascribes the corrosive action of the Vartry water supply of Dublin to the presence of minute quantities of peaty matter, which ferment slowly, with the formation of carbonic acid, as well as small quantities of nitric acid.

The destructive effect of carbonic acid has already been referred to; in swampy waters, for the reasons mentioned, it is high, and, in many well waters, it is very high. It is, moreover, very soluble in

* "The Chemistry of Humus," *Journal* of the Franklin Inst., Vol. 176, p. 565.
† *Engineering News*, Vol. LXXI, p. 354.

water, so that it is in available form to attack any iron exposed to its influence.

It can be readily understood, therefore, that, by their various secretions, plants and animals are important accessories in the corrosion of iron.

Conditions Inhibiting Corrosion.

In reviewing the conditions contributing to corrosion, it was shown that whereas dilute solutions of alkalis did not retard corrosion, strong solutions neutralize the acids and preserve the iron for an indefinite period. Mr. Allerton S. Cushman found that 5% of lime applied to boggy, sour land exerted a pronounced retarding action on the corrosion of ironwork embedded in it.* The same authority further says:

"There should be many cases where the property of alkalis to inhibit corrosion could be made of more practical use than has been done. Whenever iron posts or standards are set directly in the ground, the liberal use of slaked lime should be beneficial."

The effect of concrete in protecting iron and steel was referred to when discussing the action of two or more electrolytes in one solution.

Cast iron is obtained by pouring the molten metal into sand moulds. The outer skin, therefore, is silicious. It has long been known that silicon tends to protect iron from corrosion, and Jouve† has shown that a 20% alloy of iron and silicon is not attacked by acids, but is virtually uncorrodible. Wallace‡ refers to having seen natives in India forge iron on a stone anvil, and says this iron, which was charcoal iron, does not rust on exposure to the weather, but takes on a fine brown patina. The question was raised whether the stone anvil did not siliconize the skin of the iron. In the experiments by Messrs. McCollum and Logan§, it was found that, under a given length of exposure in soil, if the corrosion of machined cast iron be considered as 100, that of cast iron still retaining the original surface as cast would be only 93. Krohnke‖ also notes the fact that the surface formed when pipes are cast, enables them to resist attack for a long time.

Thwaite prepared a table (reproduced as Table 5) from various published data, showing well the protective effect of this skin.

TABLE 5.—RELATIVE CORROSION OF CAST IRON WITH AND WITHOUT "SKIN".

Metal	Foul sea water.	Clear sea water.	Foul river water.	Pure air and clear river water.	City air or sea air.
Cast iron.....	3.500	3.386	2.034	0.604	2.637
Cast iron (skin removed by planing).....	12.275	4.738	3.884	0.584	4.763

Silicon is an undesirable alloy for iron in many ways, so that a surface treatment, such as naturally occurs in casting, is probably the only method of making use of its rust-inhibiting properties.

Chromium, nickel, and copper, when present in small quantities, contribute greatly to the resistance of iron to corrosion. A steel containing about 1% of chromium was found by Hadfield to corrode about half as much as ordinary mild steel. Similarly, 3% of nickel added to steel reduced its relative corrosion in salt water as compared with open-hearth steel, about 50 per cent.*

Phosphorus in iron also retards corrosion, differing in this respect from sulphur, which, by forming sulphuric acid, powerfully attacks the metal.

The coating of iron with zinc and tin is also used to inhibit corrosion. Zinc is electro-positive to iron, and if the two metals are in contact, and are immersed in a corroding solution, the zinc will pass into solution and the iron will remain unaffected. Galvanizing, therefore, is not merely a mechanical shield to the iron, but protects the metal for some distance around it. It is well to emphasize this fact, as it is a point frequently misunderstood. In a pocket manual of tables and information for engineers, bearing the date of 1911, this statement occurs: "With both zinc and iron exposed and in contact with water, corrosion proceeds more rapidly than it would if the zinc were not present." This statement is absolutely misleading and erroneous.

Tin, on the contrary, is not electro-positive to iron. Being itself practically unaffected by corrosion, it protects the iron mechanically. The tin coating, as commercially applied, is full of minute pin holes.
